The morphologic features of the tetralogy of Fallot are accurately identified by two-dimensional echocardiography. A systematized sequential approach allows visualization of the underlying anatomy from different positions as well as the associated anomalies.

From the parasternal long axis view the aorta overriding the ventricular septum is readily apparent (Fig. 63–9). The degree of override is best judged from this position.[80] More than 50% override could be considered a variant of double outlet right ventricle. The aortic root appears enlarged and there is fibrous continuity between the mitral valve and the aortic valve. After surgical correction, the patch closing the ventricular septal defect is clearly profiled. This view alone is not sufficient to diagnose the tetralogy of Fallot. Other conditions with a malalignment ventricular septal defect will share the above features.

Gentle clockwise and cranial angulation of the transducer will image the right ventricular outflow tract. Information on the severity of infundibular stenosis, pulmonary valve abnormalities and the main pulmonary artery can be obtained.

Further clockwise rotation will produce a short axis view at the level of the aortic root. If the ventricular septal defect is perimembranous it is possible to demonstrate tricuspid valve to aortic valve continuity across the defect. The cranial and anterior displacement of the outlet septum is visualized (Fig. 63–10) as well as the pulmonary valve, main, and branch pulmonary arteries.[81] It is important to demonstrate continuity between the right and left pulmonary artery since in tetralogy of Fallot, the right and left pulmonary artery may arise separately from the aorta. Continuous pulmonary arteries are best imaged from a high short axis position or from the suprasternal notch (Fig. 63–11). The presence of a patent ductus arteriosus as well as postoperative information on conduits used for reconstruction of the right ventricular outflow tract may be obtained from the short axis position.

Caudal angulation of the transducer will produce a short axis image of both ventricles. The right ventricle will appear hypertrophied and may also be dilated.

From the apex, a four chamber image will outline the anatomy of the crux of the heart. Straddling of the mitral or tricuspid valves can be identified as well as the rare association of a complete atrioventricular septal defect with tetralogy of Fallot. Occasionally there is a persistent left superior vena cava draining to the coronary sinus. When present, the coronary sinus is usually dilated. Abnormalities of pulmonary venous connections are rare, but should be excluded. Careful scanning along the ventricular septum will reveal the presence of additional ventricular septal defects. Cranial angulation of the transducer will outline the left ventricular outflow tract and the malalignment ventricular septal defect. There will be fibrous continuity between the tricuspid and aortic valves if the defect is perimembranous. If the defect is muscular, there will be a muscle bar separating the tricuspid and aortic valves. Following surgical correction, the patch closing the ventricular septal defect is imaged as a bright echogenic structure.

Abnormalities of pulmonary and systemic venous return can be demonstrated from the subcostal position. This also is the best view for diagnosing atrial septal defects that are commonly associated with tetralogy of Fallot. From a subcostal four chamber view, cranial angulation and clockwise rotation of the transducer will demonstrate the overriding aortic root and the ventricular septal defect (Fig. 63–12A). Counterclockwise rotation will show the right ventricle with its inlet, trabecular, and outlet portions. The anterior deviation of the outlet septum producing infundibular stenosis is best visualized from this image (Fig. 63–12B).[82–84] The

pulmonary valve, main pulmonary artery, and proximal portions of the right and left branches (particularly in neonates and infants) are also seen.

Determination of the side of the aortic arch is very important, particularly if an infant is being referred for palliative surgery on the sole basis of noninvasive investigations. Approximately 25% of patients with tetralogy of Fallot have a right aortic arch. A left aortic arch is fully imaged from the suprasternal notch with the plane of the transducer aimed toward the angle of the left scapula. Visualization of the bifurcation of the first arch vessel will show a right brachiocephalic artery. A right aortic arch is only partially imaged from the standard position. Counterclockwise rotation of the transducer with the imaging plane toward the right will then profile the arch, the first vessel being a left brachiocephalic artery. From the suprasternal notch the right pulmonary artery is imaged below the aortic arch. Clockwise rotation of the transducer will demonstrate continuity between the right and left pulmonary artery if it is present. Growth of small pulmonary arteries can be serially assessed.

Doppler echocardiography adds hemodynamic information to the anatomical findings obtained from the cross-sectional scan. The presence of a patent ductus arteriosus as well as incompetence of the mitral and tricuspid valves is readily identified. Flow across the atrial septum can be accurately detected by color flow mapping. Color Doppler is also useful for the detection of multiple ventricular septal defects. It is possible to estimate the gradient across the right ventricular ouflow tract and systemic to pulmonary artery shunts using continuous wave Doppler.

After surgical correction of the tetralogy of Fallot, pulmonary insufficiency and residual right ventricular outflow tract obstruction are common. The severity of these hemodynamic sequelae are amenable to evaluation with Doppler techniques. After conduit reconstruction of the right ventricular outflow tract, serial Doppler studies allow detection of conduit obstruction as well as followup of the progression. The presence of residual ventricular septal defects can also be established.

In patients with tetralogy of Fallot and pulmonary atresia, the echocardiographic features are very similar except those regarding the right ventricular outflow tract and the pulmonary arteries. Atresia may occur at infundibular, valve, or pulmonary artery level. Careful scanning of the right ventricular ouflow tract from the parasternal and subcostal positions is warranted for identification of the atretic site. A blind ending infundibulum can be demonstrated, especially with combined cross-sectional echocardiography and Doppler evaluation. It is important to establish whether a main pulmonary artery is present and if there is continuity between the right and left branch pulmonary arteries.[85,86] Echocar-

diographically it can be difficult to distinguish between true pulmonary arteries and major aortopulmonary collateral vessels. The latter may often be imaged from the suprasternal notch arising from the aorta. Unfortunately, it is not possible to follow their distribution within the lungs. Color flow mapping increases the accuracy of detection of aortopulmonary collaterals and the presence of proximal stenosis within them. In tetralogy of Fallot with pulmonary atresia, the aortic arch is often right sided.

Two-dimensional and Doppler echocardiography are invaluable noninvasive techniques. In combination they provide accurate anatomic and hemodynamic data for the diagnosis and longterm followup of patients with the tetralogy of Fallot.

CARDIAC CATHETERIZATION

The diagnosis of tetralogy of Fallot is usually suspected on the basis of clinical findings and can be readily confirmed by two-dimensional and Doppler echocardiography. Cardiac catheterization and angiocardiography are important in the evaluation of the patient with tetralogy of Fallot both preoperatively and postoperatively. In the preoperative patient it is important to define the levels of stenosis in the right ventricular outflow tract and pulmonary artery[87,88] and hopefully to predict accurately whether the repair is likely to be successfully accomplished.[89–91] It is extremely important to demonstrate features such as multiple ventricular septal defects or coronary artery anomalies that might have an adverse affect on the success of surgical repair.[35,88,92] The assessment of hemodynamic result and ventricular function, residual anatomic abnormalities, and electrophysiologic studies is important in the evaluation and followup of patients postoperatively.[93–97]

Catheterization Prior to Complete Repair

A standard protocol is followed for hemodynamics and oximetry while the sites of injection and views for angiocardiography are selected to define the anatomy and associated abnormalities in tetralogy of Fallot. Catheters are usually inserted into the femoral vessels and entry into the pulmonary artery is most difficult from this position. Since crossing the right ventricular outflow tract with the catheter is sometimes associated with a hypoxemic spell, we recommend measurement of oxygen consumption and assessment of hemodynamics and oximetry at all other sites prior to attempts at crossing the right ventricular outflow tract with the catheter. In this way, even if a hypoxemic spell is induced, baseline measurements will have been obtained beforehand. In many laboratories, flow-directed balloon catheters are used for right heart procedures. In patients with tetralogy of Fallot with moderate to severe pulmonary stenosis, the right-to-left shunt will result in a flow-directed balloon catheter passing from the right ventricle into the aorta. In these patients, entry into the pulmonary artery, if desired, may be only possible with a woven Dacron or some other type of nonflow-directed catheter. It is usually possible to enter the left heart and the aorta with the venous catheter in patients with tetralogy of Fallot. Since an atrial communication, either a patent foramen ovale or atrial septal defect is commonly present, the venous catheter can be advanced across the atrial septal communication into the left atrium and from there into the left ventricle. It is also frequently possible to manipulate the catheter from the right ventricle out into the aorta. In many cases, where the atrial septum is intact and the catheter has been advanced into the aorta, it is possible to manipulate this catheter into the left ventricle across the ventricular septal defect. This is accomplished by maintaining counterclockwise twist on the catheter as it is withdrawn from the ascending aorta into the ventricle. This counterclockwise twist will result in the catheter tip flipping into the left ventricle rather than the right ventricle as it is withdrawn from the aorta.

Oxygen saturations are determined at standard sites within the cardiovascular system and the data used for calculation of pulmonary and systemic blood flow. If oxygen consumption is measured, then actual pulmonary and systemic blood flows can be calculated. Otherwise, the pulmonary to systemic flow ratio can be used. Although some patients have a balanced shunt or net left-to-right shunt, most patients with tetralogy of Fallot have a net right-to-left shunt and at least some degree of systemic arterial desaturation. The degree of right-to-left shunting can be quantified either by oximetry or by means of indicator dilution curves.

The ventricular septal defect is unrestrictive in patients with tetralogy of Fallot and thus the systolic pressures are the same in both ventricles and the aorta. If the systolic pressure is the same in the left ventricle and the aorta and higher than that in the right ventricle (and this is not an artifact of measurement), then the ventricular septal defect is somewhat restrictive and the right ventricle does not freely communicate with the aorta. Even though infundibular pulmonary stenosis is present, this raises the question as to whether or not the patient truly has tetralogy of Fallot. If the systolic pressure in the right ventricle and aorta are the same and the left ventricle pressure is higher, the possibility of double outlet right ventricle with a restrictive interventricular communication must be considered. In the rare case of tetralogy with suprasystemic right ventricular pressure, partial occlusion of the ventricular septal defect by excess, or accessory tricuspid valve tissue will be demonstrated angiographically.

If it is possible to pass a catheter into the pulmonary artery, the slow withdrawal of an end-hole catheter from the distal pulmonary arteries to the right ventricle may demonstrate additional sites of stenosis in the distal pulmonary artery, in the supravalvar region, or at the valvar level. However, the proximal infundibular stenosis and right-to-left shunt at ventricular level will make the pressure gradient across more distal areas of stenosis an unreliable measure of their severity. This is best assessed by angiocardiography. It is important to measure the pulmonary artery pressure in patients who are being considered for corrective surgery and who previously had a systemic to pulmonary artery anastomosis. This is especially true if the patient has had a Waterston, Potts, or other central shunt. Pulmonary hypertension may occur in patients who have undergone these palliative surgical procedures and if present, may be a serious complicating factor at the time of complete repair.[98,99]

Angiocardiography

Angiocardiography complements the information obtained by echocardiography and is a valuable tool for the assessment of the anatomic severity of tetralogy of Fallot and the demonstration of the nature and severity of associated abnormalities. These include definition of the levels of obstruction to right ventricular outflow, anatomy of the pulmonary arteries, and the presence of multiple ventricular septal defects or coronary artery anomalies. Stenosis in the right ventricular outflow tract is demonstrated by a selective injection in the right ventricle.[87,88,92] If movable "C-Arm" equip-

ment is available, right anterior oblique and lateral views can be used. Otherwise, with fixed bi-plane equipment, right and left anterior oblique, or anteroposterior and lateral views will demonstrate the anatomy (Fig. 63–13). To best visualize the pulmonary arteries, a combination of compound axial views, described by Bargeron et al.,[100] is used. An anteroposterior projection with about 30° of craniocaudal angulation (''sitting up'' view) will visualize the main pulmonary artery, pulmonary artery bifurcation and pulmonary artery branches (Fig. 63–14).[88,101] The left pulmonary artery is best seen if the lateral camera can be used to obtain a four-chamber view (left anterior oblique with craniocaudal angulation). It is often helpful to visualize the right ventricular outflow tract and pulmonary artery simultaneously, especially when it has not been possible to enter the pulmonary artery with the catheter. This is accomplished by a hand injection of contrast in the right ventricular outflow tract using an end-hole catheter (Lehman or Goodale) and in the compound views that have been just described.

A selective injection of contrast material in the left ventricle will demonstrate left ventricular anatomy, function, and the defect in the interventricular septum. This is best performed in the left anterior oblique view with craniocaudal angulation (four chamber or long axial oblique view) and with a complementary right anterior oblique or separate anteroposterior projection depending upon the kind of equipment that is available. The four chamber or long axial oblique projection will demonstrate the ventricular septal defect in the left ventricular outflow tract and will nicely profile the trabecular portion of the interventricular septum to evaluate for the presence of multiple or muscular ventricular septal defects.[88] Mitral-aortic valve continuity is demonstrated on the lateral view of the left ventricular injection and should be evaluated if double outlet right ventricle is suspected on the basis of other parameters or echocardiography.

Opacification of the aorta (visualized from either a ventricular injection or an ascending aortic injection) is important to document the side of the aortic arch and the anatomy of the brachiocephalic vessels. This information is important for the surgeon if a patient is to undergo a systemic to pulmonary artery anastomosis. In preparation for complete repair, it is important to determine if a patent ductus arteriosus or large systemic to pulmonary artery collaterals are present, since these vessels should be ligated at the time of operation. Lastly, the coronary artery pattern must be demonstrated in the patient who is to undergo complete repair.[88,102] Coronary artery anomalies such as an accessory anterior descending, or an anterior descending coronary artery arising from the right coronary artery, have great importance at the time of surgical repair.[34,35] In both of these cases, the anterior descending coronary artery or the accessory branch arises from the right coronary artery and crosses the right ventricular outflow tract before it follows in the normal distribution (Fig. 63–15). The potential for damage to this vessel is extremely high with a standard right ventriculotomy incision for repair of tetralogy of Fallot. Knowledge of the existence of this anomaly will enable the surgeon to modify the operative technique thus hopefully avoiding damage to a major coronary artery supplying the interventricular septum and left ventricular myocardium. Since it is usually possible to pass the catheter from the right ventricle out into the aorta, an injection with this catheter may visualize the coronary artery anatomy and also evaluate for aortic regurgitation.[88,102] If the coronary arteries cannot be demonstrated adequately, then a selective injection in the ascending aorta with a retrograde catheter is necessary. If the coronary artery pattern still cannot be visualized adequately using an aortic root injection, then selective coronary arteriography should be performed.[30,35]

In patients with tetralogy of Fallot and pulmonary atresia, most commonly, pulmonary blood flow is by means of one or more

large systemic to pulmonary collateral arteries arising from the descending thoracic aorta.[14,15,18,19,103,104] The pulmonary arteries are usually small and often are extremely hypoplastic. There are wide variations in the nature of the pulmonary blood supply (see Fig. 63–5). Collateral arteries may connect directly to a pulmonary artery and thus provide pulmonary blood flow to an entire lung. These vessels may also feed directly into a pulmonary segment resulting in either dual supply to that segment (from the collateral and from the true pulmonary artery), or may be the sole supply to that segment with the result that some portions of the lung are supplied by collaterals and other portions by a true pulmonary artery.[19,104] The precise anatomy and distribution of the pulmonary blood supply can be demonstrated angiographically. An injection of contrast in the descending thoracic aorta will serve as a screening procedure to define the number and position of systemic to pulmonary collateral arteries (Fig. 63–16). Subsequent selective injections in each of these collateral vessels are important to demonstrate the size and distribution as well as areas of stenosis in the collateral artery.[105] True pulmonary arteries are often still unidentified following the selective injections in the systemic to pulmonary collaterals. Pulmonary vein wedge angiography, which is described in detail in another chapter in this book, is often necessary to define the true pulmonary arterial artery.[106] Demonstration of the size, distribution, and continuity between right and left pulmonary arteries is important information in the surgical management of patients with tetralogy of Fallot and pulmonary atresia and will be discussed later in this chapter.

Other Catheterization Procedures—Preoperative or Postoperative

Electrophysiology

Most centers do not routinely perform intracardiac electrophysiologic studies postoperatively despite the fact that a significant incidence of atrioventricular conduction abnormalities have been reported following complete repair of this anomaly.[72–74] Neches et al.[107] and others[108] have reported that at least 25% of postoperative patients show abnormalities of atrioventricular conduction that were not present preoperatively. Electrophysiologic screening procedures are easily performed with a single catheter and may identify abnormalities that warrant further, more sophisticated evalu-

ation. The studies performed with a single catheter include obtaining a His bundle electrogram, measurement of resting AH and HV intervals, and incremental atrial pacing to determine AV node refractoriness and sinus node recovery time. Although the significance of the abnormalities that have been found in these patients is still unknown, the high incidence of abnormalities found in this group and not present in other groups of postoperative patients are bothersome and indicate a subgroup that may be at greater risk for problems in the future.

Ventricular arrhythmias may be found following repair of tetralogy of Fallot. It has been suggested that the finding of premature ventricular beats on resting or exercise electrocardiography may be a marker for those patients who may develop serious ventricular arrhythmias and sudden death.[76,77] An intracardiac electrophysiologic study would be indicated for those postoperative patients in a high risk category such as those with previous episodes of syncope or suspected arrhythmia, or to facilitate the selection of pharmacologic therapy in patients with serious and life-threatening arrhythmias.

Interventional Catheterization Procedures

Percutaneous balloon angioplasty has become widely used in management of coronary artery disease and valvar stenosis in adults and in a number of congenital cardiac abnormalities including valvar pulmonary stenosis, valvar aortic stenosis, and coarctation of the aorta.[109–111] This technique has been used in a few preoperative patients with tetralogy of Fallot[112] and successful balloon dilatation of a stenotic Blalock-Taussig systemic to pulmonary artery anastomosis has also been reported.[113] In addition, balloon dilatation of residual pulmonary artery stenosis in patients who have undergone complete repair of tetralogy of Fallot may be an important future application.[114] In the past, balloon dilatation of pulmonary artery stenosis usually has not been successful due to the inability to maintain the area of pulmonary artery stenosis in its dilated state after deflation and removal of the balloon dilatation catheter. A potentially valuable technique that is currently under investigation involves the use of a wire mesh stent that surrounds the surface of a deflated balloon dilatation catheter.[115] When this device is inserted into a stenotic area of pulmonary artery and the balloon inflated, the stent assumes a new and larger diameter. When the balloon is deflated the metal stent retains the enlarged diameter and thus prevents the surrounding stenotic area of pulmonary artery from returning to its previous size. This technique holds particular promise for the treatment of areas of distal pulmonary artery stenosis in patients who have undergone complete repair. These areas of stenosis are often at the site of distal anastomoses of the pulmonary artery with conduits or patches and are usually not amenable to further surgical intervention. Finally, coils may be used to occlude collateral vessels that persist after complete repair.

MEDICAL MANAGEMENT OF TETRALOGY OF FALLOT

Natural History

The presentation and clinical course of patients with tetralogy of Fallot depend on the degree of pulmonary stenosis. Although many patients are acyanotic in early infancy, the subpulmonary stenosis tends to be progressive and usually results in the appearance of cyanosis during infancy or early childhood. Prior to the development of systemic to pulmonary artery anastomoses in the mid 1940s, approximately 50% of patients with tetralogy of Fallot died in the first few years of life and it was unusual for a patient to survive past the third decade.[116,117] Mortality was usually either a direct consequence of hypoxia, secondary hematologic changes, or problems such as infectious endocarditis or brain abscess.[118,119] With the advent of palliative procedures and complete repair, which now is possible even during infancy and early childhood, 85% or more of patients with tetralogy of Fallot would be expected to survive to adulthood. These various surgical modalities that have had such a profound affect on the survival of patients with tetralogy of Fallot, as well as many other types of congenital heart disease, will be described in this section following a discussion of the medical management of the effects of hypoxia during infancy and childhood.

Hypoxia and Polycythemia

In patients with tetralogy of Fallot, the treatment of significant resting hypoxia and/or hypercyanotic spells is surgical. Since the mid 1940s, systemic to pulmonary artery anastomoses have generally provided adequate palliation and since the mid 1950s, corrective procedures have been possible. The resting systemic arterial oxygen saturation is quite variable in asymptomatic patients with tetralogy of Fallot and may be from the low 70s to the mid 90s depending upon the degree of pulmonary stenosis. Any type of physical activity, either feeding or crying in the infant or other exercise in a child, results in a fall in the systemic arterial oxygen saturation. Although these patients certainly have less exercise capacity and stamina than their normal and healthy siblings and peers, this systemic desaturation does not seem to have a great effect on growth and development in many cases. However, some investigators have found that patients with the tetralogy of Fallot have delayed growth or development as compared to their normal peers even when they have had adequate palliation.[120,121] Unfor-

tunately, it is extremely difficult to determine the specific etiology of these developmental problems. As was mentioned earlier in this chapter, many patients with tetralogy of Fallot have other associated congenital anomalies. In addition, although it is possible that growth and development problems are related to cyanosis, these patients also may undergo multiple cardiovascular procedures. Thus some of these problems may be related to the surgical procedures, to the timing of these procedures, or possibly even to the psychosocial abnormalities that are known to occur in this group of patients.[122–124]

Polycythemia is a major physiologic consequence of the presence of hypoxemia. In general, patients with tetralogy of Fallot and an adequate systemic oxygen saturation at rest, have an increased red blood cell count and a hemoglobin in the range between 15 and 17 g/dL. This corresponds to a hematocrit between 45 and 50%. When the hematocrit is in this range, the increased number of red blood cells is sufficient to provide adequate peripheral oxygen delivery while it is not so high as to produce the serious side effects of polycythemia. However, when the hematocrit is above 60%, the viscosity of blood increases geometrically for each increase in the percent hematocrit. This tends to provide a substantial increase in blood viscosity especially when the hematocrit is over 65%.[125] The increased viscosity results in peripheral sludging of blood and places the patient at greater risk for having the neurologic complications that will be described below. Another important complication of high hematocrit and high blood viscosity is the alteration of clotting factors that occurs in these patients.[126,127] When the hematocrit is 65% or higher, there is an alteration of the coagulation status with increased prothrombin time, low platelet count, decreased concentration of fibrinogen and other coagulation factors. This most likely occurs as a result of a subclinical consumption coagulopathy.[127,128] Although this altered coagulation state is usually of little consequence, it is a serious problem for the patient who is about to undergo open heart surgery. Thus, when a polycythemic patient with a hematocrit of over 60% is about to undergo complete surgical repair rather than a systemic to pulmonary artery shunt, it is important to check the patient's coagulation profile about a month prior to operation. If it is found to be abnormal, then phlebotomy and an exchange with a plasma substitute is performed in some centers approximately 1 week to 10 days prior to operation. Reduction of the hematocrit below 60% serves to improve the cardiovascular status,[129] reduce peripheral sludging, and will improve the patient's coagulation status, thus minimizing the risk of bleeding diathesis postoperatively.[130]

Neurologic Complications

Patients with tetralogy of Fallot, especially those with marked polycythemia, are at risk for a number of neurologic problems, some of which are readily reversible and others that have permanent residua.[119,120] Headaches are a common complaint of patients with polycythemia (especially when their hematocrit is over 65%) and these are probably related to the sludging of blood in the capillary circulation of the brain. These symptoms are usually relieved by the reduction or elimination of cyanosis and polycythemia that occurs as a result of palliative or corrective surgical procedures. If the systemic arterial oxygen saturation cannot be improved by surgical means, such as sometimes occurs in patients with tetralogy of Fallot and pulmonary atresia, the symptoms related to marked polycythemia are temporarily reversed following phlebotomy procedures. In these patients it may be necessary to perform routine phlebotomy and exchange transfusion with a plasma substitute in order to maintain the hematocrit in a range at which the patient will remain free of symptoms.

Delayed intellectual and/or motor development and seizures may occur in patients with tetralogy of Fallot.[118,121] It is possible that these problems are related to the systemic hypoxemia that many of these patients have during infancy.[122] However, it must be remembered that in patients with tetralogy of Fallot, as in other patients with cyanotic congenital heart disease, there is a direct route from the systemic venous circulation to the systemic arterial circulation and thereby to the brain. Spontaneous intravascular thromboses, either arterial or venous, can occur in the presence of severe polycythemia. Thus, small intracerebral vessel thrombosis or peripheral venous thrombosis with systemic arterial embolization, can occur in the absence of an apparent major clinical event and yet result in these neurologic abnormalities. In the same respect, these patients may have inadvertent systemic arterial embolization during one of their cardiac catheterizations or surgical procedures. Cerebrovascular accidents, which are more severe and permanent neurologic complications, may have the same underlying mechanism. These are often temporally related to procedures although as many as 50% can occur spontaneously.[118]

Although the majority of these complications are related to procedures or occur in polycythemic patients, anemia may also be a factor.[118,119] While a hemoglobin concentration of 12 to 14 g/dL is normal for a noncyanotic patient, this level of hemoglobin, or lower, represents a significant relative anemia for a patient with tetralogy of Fallot who is quite cyanotic. It has been our experience and that of others, that relative anemia in a cyanotic patient is as much a risk factor for a cerebrovascular accident as is severe polycythemia. Thus, patients with significant resting cyanosis and a hemoglobin at either extreme (with a hemoglobin below 15 grams or above 20 grams), are at risk for the development of neurologic complications especially during infectious illnesses. Careful attention must be paid not only to polycythemia but also to relative anemia. If a patient with tetralogy of Fallot and hypoxemia is found to have a hematocrit less than 15 g/dL, supplemental oral iron therapy should be instituted to raise the hemoglobin and hematocrit to what is considered to be an appropriate level for that patient's degree of cyanosis and hypoxemia.

Infection is another important cause of neurologic complications in patients with tetralogy of Fallot. As a result of the right-to-left shunt, there is a direct route from the systemic venous circulation into the systemic arterial circulation and to the brain. Thus, bacteremia that is produced by systemic infectious illnesses, or by infectious endocarditis, produces seeding of the systemic circulation and may result in a brain abscess.[131] The presence of headache or other neurologic symptoms in any preoperative patient with tetralogy of Fallot, even in the absence of fever, warrants investigation into the possibility of this serious and potentially fatal complication.

Paroxysmal Hypoxemic Spells

The underlying mechanisms that result in "tetralogy spells" are described in this chapter in the Physiology and Hemodynamics section. Regardless of the underlying mechanism responsible for these spells, the clinical manifestations are similar and are characterized by increasing cyanosis and an increased rate and depth

of respiration. Hypoxemic spells can occur in any patient with an intraventricular communication and a right-to-left shunt at ventricular level and thus may be found in patients who are acyanotic at rest as well as in patients with tetralogy of Fallot and pulmonary atresia. As a result of the increased right-to-left shunt at ventricular level, whatever the underlying mechanism, forward flow across the right ventricular outflow tract is reduced.

Hypoxemic spells are usually self-limited and of less than 15 to 30 minutes duration. In addition to trying to comfort the patient during one of these episodes, it is also advisable to have the child assume a knee–chest position. In an older child, this can be accomplished by squatting, or by raising the knees to the chest in the supine or prone position. Similarly, the infant or small child can be held over the parent's shoulder with the knees drawn up against the infant's chest. It is likely that squatting, or assuming a knee–chest position, causes increased peripheral resistance in the lower extremities and this, in turn, promotes an increase in pulmonary blood flow.

In a hospital situation, oxygen is administered by face mask during a hypoxemic spell; if the oxygen does not appear beneficial, it should be removed since it may irritate the child. If the patient's hypoxemic episode does not appear to be resolving, morphine sulfate can be administered either intramuscularly, subcutaneously, or intravenously in a dose of 0.1 mg/kg of body weight. The effectiveness of morphine sulfate in treating a hypoxemic spell has been known for many years, but its exact mechanism of action is still unclear. It may have a direct relaxing effect on the subpulmonary infundibulum or its action may be mediated through an effect on the central nervous system, or by a peripheral vagotonic effect. Since morphine can be administered intramuscularly, it is valuable to use this drug for initial management of a hypoxemic spell when an intravenous route is unavailable. Once an intravenous line has been placed, the dose of morphine sulfate again can be repeated or additional pharmacologic agents can be administered directly into the venous system. It is important to remember that metabolic acidosis appears rapidly after the onset of a hypoxemic spell and thus sodium bicarbonate in a dose of 1 mEq/kg can be given empirically as soon as intravenous access is available. If these measures are unsuccessful, a beta-blocking agent such as propranolol is extremely valuable in the management of a hypoxemic spell.[132] Propranolol is given intravenously to a maximum total dose of 0.1 mg/kg of body weight. It must be remembered that 1 mg intravenously is the standard adult dose of propranolol. Thus, the total calculated dose should be diluted with 10 mL of fluid in a syringe and no more than half of the calculated dose should be given initially as an intravenous bolus. The remainder can be given slowly over the next 5 to 10 minutes if it appears that the initial intravenous dose has not been effective in starting to reverse the hypoxemic spell. Any time intravenous propranolol is used, isoproterenol should also be available to reverse the effects of overdosage of the beta-blocking agent.

In the same way that the knee–chest position improves pulmonary blood flow by increasing systemic resistance, intravenous infusion of fluid for volume expansion, or the administration of a peripheral vasoconstrictor such as phenylephrine, will have a similar effect. In the unusual circumstance where all of these physical and pharmacologic maneuvers have been unsuccessful, general anesthesia can be utilized to abort a hypoxemic spell. In this situation, an emergency systemic pulmonary artery anastomosis should also be considered. Fortunately, this has been rarely necessary in our experience.

Propranolol has also been used in the long-term nonoperative management of paroxysmal hypoxemic spells.[133,134] It is administered orally in a dose of 1 to 4 mg/kg of body weight per day in three or four divided doses. Its major usefulness would be in the management of hypoxemic spells in patients who were not candidates to have surgical management. For example, in a patient who has normal or increased pulmonary blood flow and is too small for complete repair, a systemic to pulmonary artery anastomosis might result in excessive pulmonary blood flow. In such a patient, the use of propranolol might enable an attempt at complete repair to be deferred until the patient was older and the risk of operation lower.

SURGICAL MANAGEMENT OF TETRALOGY OF FALLOT

Definitive surgical repair is the ultimate goal of the management of tetralogy of Fallot and tetralogy of Fallot with pulmonary atresia. In the asymptomatic patient, the timing of surgical management remains controversial with some centers advocating a complete repair in infancy while others prefer to perform repair during early childhood. Most would agree that some form of surgical management is indicated for the symptomatic patient with severe cyanosis, polycythemia or hypercyanotic "spells." A definitive, single-stage operation is preferred at any age but may not be possible for any of a number of reasons that include the size of the patient, small caliber of the pulmonary arteries, or coronary artery anomalies. Surgical expertise in the individual center must also be considered. These factors will be discussed in more detail in the section on Complete Repair. When surgical intervention becomes necessary in the symptomatic patient who is not a good candidate for complete repair, a palliative procedure is performed to increase pulmonary blood flow until definitive surgical correction is possible.

Systemic to Pulmonary Artery Anastomoses

Subclavian to Pulmonary Artery Anastomoses

In 1945, Blalock and Taussig[2] described the surgical creation of an artificial ductus arteriosus using an end-to-side anastomosis between the subclavian artery and the pulmonary artery (Fig. 63–17). This procedure marked the beginning of the era of surgical management of complex cyanotic congenital heart disease. The technique that is currently employed to perform this "classic" Blalock-Taussig (B-T) shunt is similar to that originally described by Blalock and Taussig with only a few modifications. The procedure is performed through a lateral thoracotomy on the side opposite the aortic arch. This is preferred because the subclavian artery originating from the brachiocephalic artery has more mobility. In addition, the angle from the brachiocephalic artery is less acute and thus kinking is less likely as compared to using the subclavian artery that arises directly from the aorta on the same side as the aortic arch. The subclavian artery is divided at the origin of its branches and the vertebral artery is ligated. This latter step is essential to avoid the problem of "subclavian steal" (see below) postoperatively. The proximal stump of the subclavian artery is then anastomosed to the side of the right pulmonary artery just proximal to the first branch.

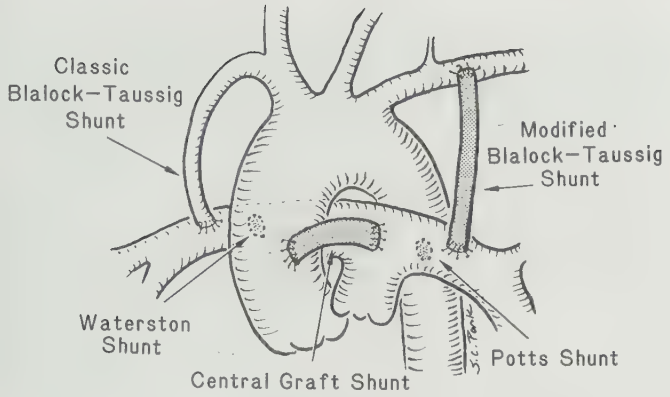

Fig. 63–17. Diagram illustrating the various systemic to pulmonary artery anastomoses.

The classic Blalock-Taussig shunt can be performed in infants and children and provides excellent long-term palliation.[135,136] With this procedure, as compared to other forms of systemic to pulmonary artery anastomoses, the size of the patient's subclavian artery, rather than the size of the surgical anastomosis will limit the volume of pulmonary blood flow. Thus, the incidence of complications from excessive pulmonary blood flow such as congestive heart failure and pulmonary hypertension are extremely low following the Blalock-Taussig anastomosis.[98,99]

In infants younger than 6 months of age, especially in the newborn, the subclavian artery is of relatively small size and short length. Although the classic B-T shunt can be performed successfully, especially with the currently available microsurgical techniques, this shunt may be prone to thrombosis or problems with inadequate blood flow. As a result, a modified form of Blalock-Taussig anastomosis has become popular over the last decade for use in patients under 6 months of age, especially small infants.[137–140] This procedure is usually performed on the same side as the aortic arch as compared to the opposite side in the classic B-T shunt (Fig. 63–17). This modified B-T shunt consists of an interposition graft of synthetic material, usually expanded polytetrafluorethyelene (PTFE or Gore-Tex) between the subclavian artery and the pulmonary artery. A prosthesis of greater diameter than that of the subclavian artery, usually 5 to 6 mm, is sutured to the side of the undivided subclavian artery, with the other end of the graft sutured to the side of the pulmonary artery. This modified B-T shunt has the advantage of the classic type of shunt in that the subclavian artery is still the limiting factor in pulmonary blood flow. On the other hand, it is easier to perform in small infants, does not require sacrificing the subclavian artery and allows for a larger surgical anastomosis thus providing for a potential increase in the magnitude of pulmonary blood flow as the patient grows and the subclavian artery increases in size.

In addition to the low incidence of problems from excessive pulmonary blood flow, both forms of Blalock-Taussig shunt also have additional advantages compared to the other types of systemic to pulmonary artery anastomoses (see below). These include the fact that the pericardium is not entered thus avoiding problems with pericardial adhesions at the time of future procedures. In addition, these B-T shunts are easiest to close at the time of complete repair simply by ligation of the distal portion of the shunt just proximal to the anastomosis with the pulmonary artery. Although some distortion of the pulmonary artery usually occurs with all forms of systemic to pulmonary artery anastomoses, this is usually limited to "tenting" of the pulmonary artery in patients who have had a B-T shunt as compared to the more serious distortion and kinking of the pulmonary arteries that occurs with other procedures.

In addition to problems of excessive pulmonary blood flow and distortion of the pulmonary arteries, a number of less serious complications occur following B-T anastomosis. Since the phrenic nerve, the recurrent laryngeal nerve and the cervical sympathetic chain are found in the area of the dissection, complications related to dysfunction of these nerves may follow such operations. These include diaphragmatic paralysis (phrenic nerve), vocal cord paralysis (recurrent layrngeal nerve), and Horner's syndrome (ptosis, miosis, and anhydrosis—cervical sympathetic chain).[51,136,139] Chylothorax or hemothorax are relatively short-term problems that can occur following all shunt procedures. Problems specifically related to use of the subclavian artery are uncommon but include subclavian vascular insufficiency as a result of poor collateral blood flow (even less common with the modified form of shunt that does not sacrifice the subclavian artery) and subclavian steal syndrome. This latter problem is a form of basilar artery insufficiency as a result of "vertebral steal" from the cerebral circulation to provide collateral flow into the distal subclavian artery.[141] This problem should no longer occur following a B-T shunt since the vertebral artery is almost always ligated at the time of operation.

Aorta to Pulmonary Artery Anastomoses

A number of other procedures have been described that involve either direct connection or graft interposition between the aorta and the pulmonary artery (Fig. 63–17). The Potts operation[3] was first described in 1946 shortly following the Blalock-Taussig operation, and consists of a direct anastomosis between the descending aorta and the left pulmonary artery. An intrapericardial, direct anastomosis between the ascending aorta and the right pulmonary artery was described by Waterston in 1962[142] and Cooley and Hallman in 1966.[143] The central aortopulmonary shunt followed the introduction of polytetrafluorethylene (PTFE or Gore-Tex) and is similar to the Waterston shunt but instead is a graft interposition between the ascending aorta and the right or main pulmonary artery.[144,145]

For approximately two decades following its introduction, the Potts anastomosis was quite popular and was the procedure of choice in many centers for infants under one year of age. This procedure was recommended because of the small size of the subclavian artery and concern about poor success with the B-T shunt in this age group.[146] Although the Potts operation provided excellent palliation, it was difficult to take down this anastomosis at the time of complete repair. It thus became much less frequently performed after the mid 1960s when the ascending aorta to right pulmonary artery shunt became popular. This latter procedure, the Waterston anastomosis, also was easy to perform in the small infant but was more easily closed from the median sternotomy approach at the time of corrective surgery. Since the late 1970s, the central shunt using a graft interposition has been used for similar reasons. In contrast to the Blalock-Taussig anastomosis where the pulmonary blood flow is limited by the size of the patient's subclavian artery, the size of the aortopulmonary communication with these other anastomoses is controlled by the tech-

nique of the surgeon. On occasion, the anastomosis would be too small and the procedure would not adequately relieve the patient's cyanosis. More commonly, excessive pulmonary blood flow from a large anastomosis resulted in congestive heart failure in 20% or more of survivors following the Potts or Waterston anastomosis.[135,146–148] Pulmonary hypertension, as a result of this excessive pulmonary blood flow, led to the development of pulmonary vascular disease in many of these patients.[146–148] An unusual problem has also been encountered following the Potts anastomosis. Some patients have late development of pulmonary hypertension or congestive heart failure as a result of progressive enlargement of the anastomotic channel some years later.[146]

Distortion of the pulmonary artery occurs at the site of anastomosis following most shunt procedures but is not usually an important problem with the classic Blalock-Taussig, modified Blalock-Taussig or central shunts. On the other hand, significant acquired pulmonary artery stenosis has been found following the Potts and particularly following the Waterston anastomoses.[135,147,148] The central Gore-Tex shunt does not seem to have as much a problem with either excessive pulmonary blood flow or distortion of the pulmonary artery as compared to the Waterston or Potts anastomosis. Early results with this procedure from many centers were disappointing, but subsequent modifications of the surgical technique have demonstrated excellent palliation, especially in the very small infant in whom it may be more difficult to perform a modified Blalock-Taussig shunt.[145]

Complete Repair

Definitive surgical repair of tetralogy of Fallot consists of closure of the ventricular septal defect and relief of the right ventricular outflow tract obstruction. The first successful open intracardiac repair of tetralogy of Fallot was performed by Lillehei in 1954 by means of "controlled cross-circulation" using another human as the "oxygenator."[4] The pump oxygenator was first used by Kirklin et al. at the Mayo Clinic in 1955.[20] In the more than three decades since then, major changes have occurred with the addition of techniques such as patch enlargement of the right ventricular outflow tract, transannular outflow patches and the use of conduits or homografts in the management of severe diffuse outflow obstruction or pulmonary atresia. Together with advances in surgical technique, cardiopulmonary bypass and intraoperative management, major advances in anesthesia and postoperative care have resulted in the expectation that over 90% of patients who undergo complete repair of tetralogy of Fallot will survive to adulthood with a good long-term functional result.[148]

Primary Repair versus Palliation

It is generally agreed that definitive repair should be performed as a primary procedure at any age if the operation can be performed at a low risk and with a reasonable expectation of good result. However, the criteria for patient selection and timing of complete repair are still controversial. Some groups have advocated primary repair of tetralogy of Fallot in symptomatic infants with favorable anatomy under a year of age, regardless of size.[150–152] Contraindications would include an anterior descending coronary artery arising from the right coronary artery, severely hypoplastic pulmonary arteries, or pulmonary atresia. Kirklin et al.[153,154] have studied the incremental risk factors involved in performing primary repair at a young age. They concluded that primary repair without a transannular patch was as safe as a two-stage approach (shunt then repair) when an infant was over 6 months of age (0.35 m^2). When a transannular patch was necessary for primary repair, the two-stage approach was felt to be safer when an infant was under 9 months of age or had a body surface area of less than 0.48 m^2. In addition to small size of the pulmonary arteries and/or the pulmonary valve annulus, other factors associated with an increased risk of early repair include: Other abnormalities of the pulmonary arteries such as anomalous origin of one artery, peripheral pulmonary arterial stenoses, or the presence of major associated anomalies. Despite all of these studies and many others that have not been quoted, the ideal criteria for primary repair versus a two-stage operation have not yet been determined, and must be individualized by center. The size of the pulmonary arteries seem to be the major limiting factor and the question "How small is too small?" remains unanswered.

Operative Procedures

Complete intracardiac repair consists of patch closure of the ventricular septal defect and relief of the right ventricular outflow tract obstruction. In patients over 1 year of age, most surgeons use conventional cardiopulmonary bypass with mild to moderate hypothermia (25 to 30°C). Cold cardioplegia together with topical cooling may also be used.[20] These latter techniques provide myocardial protection and increase the allowable time of anoxic arrest due to aortic cross clamping. Profound hypothermia with circulatory arrest is generally used in infants under 1 year of age[151,152] and some centers use profound hypothermia with low flow cardiopulmonary bypass in all but small infants under 4 months of age.[153] In most cases, especially when there are multiple levels of pulmonary stenosis, a vertical incision in the right ventricle is used for repair. This vertical incision provides excellent exposure and is useful if a transannular outflow patch is found to be necessary.[20] A transverse right ventriculotomy is preferred by some surgeons especially when the use of a transannular outflow patch is not planned. This latter type of incision is mandatory in the situation where an anomalous coronary artery crosses over the right ventricular outflow tract and might be injured by a vertical incision. The right atrium is usually opened during the operation to close an atrial septal defect or to suture a patent foramen ovale. Transatrial closure of ventricular septal defects is now commonplace and some centers have reported complete repair of tetralogy of Fallot using this approach.[20,155,156] If the patient has had a prior systemic to pulmonary artery anastomosis, the necessary dissection in the preparation for closure of the shunt is performed prior to the institution of cardiopulmonary bypass. Once this has been accomplished and bypass has been established, this shunt is then closed. This is done by direct vision, and an accompanying pulmonary arterioplasty may be necessary in patients who have undergone a Waterston or Potts anastomosis while ligation of the distal anastomosis is usually sufficient in patients who have classic or modified B-T shunt or a central shunt.

The approach to closure of the ventricular septal defect and management of right ventricular outflow obstruction is similar regardless of whether a transatrial or ventriculotomy approach is used. After the initial incision is made and the internal anatomy of the right ventricle is inspected, resection of infundibular and other hypertrophied muscle bands is carried out to enhance visualization of the ventricular septal defect and facilitate its repair.

The ventricular septal defect is closed using a patch of synthetic material, either Dacron or Teflon. The patch is sutured on the right ventricular side of the ventricular septal defect with particular care taken to avoid injury to the aortic valve leaflets or to the conduction system. In a patient with a membranous ventricular septal defect, the bundle of His runs along the posteroinferior margin of the defect and the crest of the interventricular septum. Sutures are placed superficially and as far to the right ventricular side of the defect as possible to avoid damage to this structure.

Adequate relief of right ventricular outflow obstruction is essential for successful repair of tetralogy of Fallot. Isolated infundibular or valvar stenosis may be present, but more commonly additional areas of stenosis are present at the level of the pulmonary valve annulus, or in the pulmonary arteries. Pulmonary arterial stenosis may be supravalvar, peripheral, or the pulmonary arteries may be diffusely hypoplastic. It is not unusual for multiple levels of stenosis to be present in the same patient. On some occasions, infundibular resection alone is sufficient to relieve the subpulmonary stenosis, but placement of a patch to further widen the right ventricular outflow tract is generally necessary. In the past, autologous pericardium has been used for this outflow patch but this material has a tendency to aneurysmally dilate on long-term followup, especially if there is residual stenosis. Many centers have thus begun to use a patch of synthetic material, either Dacron or Gore-Tex, or bovine pericardium, instead of autologous pericardium. The pulmonary valve is also inspected and valvar stenosis is relieved as much as possible. If further sites of downstream obstruction are present and these preceding measures are not sufficient enough to lower the right ventricular pressure, it may be necessary to extend the outflow tract patch across the pulmonary valve annulus, onto the pulmonary artery (Fig. 63–18). When pulmonary artery hypoplasia is present the patch is extended onto the pulmonary artery branches.

In infants where transannular patching increases the risk of operation to such a degree that a two-stage operation may be safer,[153] or in other patients where diffuse hypoplasia of the pulmonary arteries may preclude a successful repair at any age, prediction of the postoperative right ventricular pressure would have considerable value. Kirklin et al.[153] have suggested that a postoperative right to left ventricular pressure ratio ($P_{RV/LV}$) of less than 0.75 will be associated with a good functional result if the ventricular septal defect is adequately closed and the pulmonary valve ring is intact. To determine whether a transannular outflow patch would be required to relieve a postoperative $P_{RV/LV}$ of greater than 0.75, intraoperative measurement of the pulmonary annulus by means of Hegar dilators has been used. A pulmonary valve annulus that is less than 50% of the diameter of the ascending aorta,[156] or less than a minimum acceptable diameter from a table of normal values,[157] has been used as an indication for the necessity of a transannular outflow patch to achieve a successful surgical result with low mortality. Other centers have used different decision approaches.

On the other hand, in the infant who requires surgical intervention, or at any age when significant pulmonary artery hypoplasia is present, preoperative prediction of a postoperative $P_{RV/LV}$ greater than 1.0 would be of considerable value. In these patients, a palliative procedure would be indicated instead of an attempt at complete repair that might well be unsuccessful. A number of methods have been developed to predict the ratio of right-to-left ventricular pressure after repair on the basis of preoperative cineangiographic measurement. Blackstone et al.[91] have developed a formula to predict postrepair $P_{RV/LV}$ related to the diameter of the right and left pulmonary arteries and the pulmonary valve annulus as measured from preoperative cineangiograms and normalized to the patient's descending thoracic aorta. Another approach was taken by Nakata et al.[89] who calculated the pulmonary artery area index by measurement of right and left pulmonary arteries from preoperative cineangiograms. Although their index was not used to predict postoperative right ventricular pressure, those patients with a pulmonary artery area index of less than 60% of normal

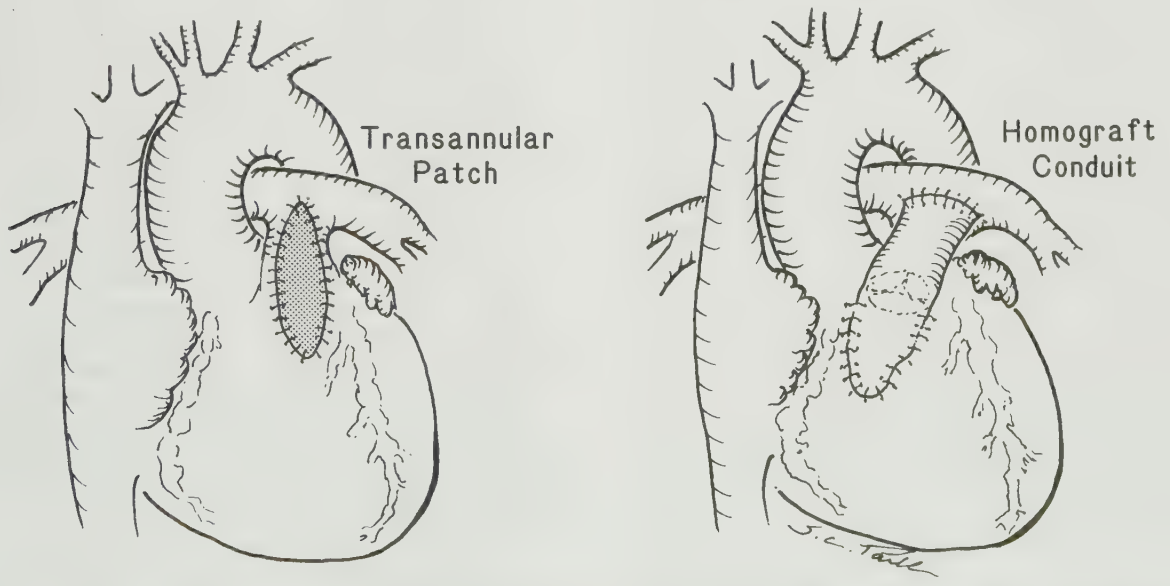

Fig. 63–18. Diagram illustrating surgical management of severe right ventricular outflow obstruction. Left: Transannular outflow patch; Right: Use of an aortic homograft conduit.

either had severe problems with low cardiac output and congestive heart failure or died in the postoperative period. Naito et al.[90] used still another method, the calculation of left ventricular end diastolic volume index, and suggested that those patients with an index of less than 30 mL/m^2 were not adequate candidates for complete repair and should undergo palliation if a surgical procedure was necessary.

Although all of these methods for estimating the success of complete repair have considerable influence on the type of procedure performed in infants and small children, complete repair is usually attempted in older children. In general, the relief of right ventricular outflow tract obstruction with a transannular outflow patch is well tolerated despite the presence of postoperative pulmonary regurgitation.[93,149] However, some patients will poorly tolerate the postoperative pulmonary regurgitation especially if there is increased pulmonary vascular resistance from a previous systemic to pulmonary artery shunt, or distal pulmonary artery stenosis. In these patients, a valved external conduit, either a Dacron conduit with a porcine heterograft valve or a homograft, has been used successfully.[158,159] Other indications for use of an external conduit include repair in a patient with an anomalous anterior descending coronary artery that arises from the right coronary artery, crosses the right ventricular outflow tract, and thus interferes with adequate relief of the outflow obstruction by standard techniques[31,34]; or in patients with tetralogy of Fallot and pulmonary atresia.

Pulmonary Artery Hypoplasia or Pulmonary Atresia

In some patients with severe pulmonary artery hypoplasia or with pulmonary atresia, continuity between the right ventricle and the pulmonary arteries can be achieved at definitive repair using a transannular outflow patch.[160,161] For this to be possible there must be a pulmonary artery trunk with confluent central pulmonary arteries. In these cases, surgical correction does not differ from that of other patients with tetralogy of Fallot requiring a transannular patch. More commonly, a conduit connecting the pulmonary arteries to the right ventricle is required for adequate relief of the obstruction[160,161] (see Fig. 63–18). Reconstruction of the right ventricular outflow tract using a valveless conduit was first reported by Rastelli in 1965.[162] The most commonly used conduits in current clinical practice are valved. They are either made of Dacron with porcine or bovine valves, or aortic or pulmonary homografts.

A number of complications have been related to the use of Dacron conduits. One of the reasons for failure of these conduits is improper positioning below the sternum. Ideally they should be toward the left of the sternum in order to avoid stenosis produced by sternal compression.[163] The development of gradients within the conduits appears to be a function of time. Conduit failure as high as 30% in 6 years has been reported.[164] Stenoses may occur at the site of conduit anastomosis with the right ventricle, with the pulmonary arteries and even within the conduit itself.[165] Intraconduit obstruction is usually related to calcification of the heterograft valve or to a consequence of a hypertrophic neointima that develops inside the conduit. This neointima can become obstructive per se, but it is also susceptible to dissection with resultant obstruction of the conduit. This can occur spontaneously or at the time of cardiac catheterization. Conduit valve insufficiency is very common.

The use of cryopreserved, antibiotic sterilized aortic and pulmonary homografts has become increasingly popular. Even though calcification of the homografts leading to homograft stenosis is a well-recognized problem, the incidence of reoperation following the use of these conduits appears to be lower.[166,167] Homograft valve stenosis and insufficiency also appear to be less of a problem. The use of a pulmonary homograft is particularly attractive in patients with severe stenosis at the bifurcation of the main pulmonary artery or when the right and left pulmonary arteries are discontinuous.

Care must be taken at the time of establishing continuity between the right ventricle and the pulmonary arteries if there is severe proximal pulmonary artery hypoplasia. These patients usually have dual pulmonary blood supply from true pulmonary arteries and major aortopulmonary collateral arteries. At least half of the segments of both lungs must be supplied by true pulmonary arteries. In these patients the predicted postoperative $P_{RV/LV}$ may be very high. Intraoperative $P_{RV/LV}$ of > 0.7 is associated with a high surgical mortality. When found, it is advisable to create a hole in the patch closing the ventricular septal defect to act as a "runoff" for the right ventricular hypertension.[168]

The presence of major aortopulmonary collateral arteries requires special management considerations. Before any surgical procedure involving the use of the aortopulmonary collaterals can be undertaken, exact definition of the segments of lung supplied by true pulmonary arteries and those supplied by collateral vessels is mandatory. This is achieved at the time of the cardiac catheterization with selective injections in the pulmonary arteries and the different collateral arteries. Most aortopulmonary collateral arteries have an area of stenosis, reducing the pressure in these vessels and protecting the pulmonary vascular bed that it supplies from developing pulmonary vascular disease. Some segments of lung may be supplied by unobstructed collateral arteries and face systemic pressures. These segments are at risk of developing pulmonary vascular disease.

As much of the pulmonary vascular bed as possible should receive its blood flow from the right ventricle. This gives rise to the concept of "unifocalization" of the pulmonary blood supply. This requires connecting the major aortopulmonary collateral vessels to the true pulmonary arteries at the level of the hilum. This type of surgery is technically difficult since many of the collateral vessels follow an intraparenchymal course.[169] If a lung segment has a dual supply, and thus receives blood flow from the true pulmonary arteries as well as from collateral arteries, then the collateral vessel can be safely ligated. Some collateral arteries may not be accessible to establishing continuity with the central pulmonary arteries and need to remain intact at the time of complete repair. These patients may have excessive pulmonary blood flow and develop congestive cardiac failure. Surgical ligation or embolization of these vessels at the time of postoperative cardiac catheterization would be indicated. The adequacy of alternative blood supply to the lung segment that is being embolized must be established prior to any of these procedures since pulmonary infarction has been described after ligation of a collateral that was the sole supply to a lung segment.[160,161] Successful embolization has been reported using tissue adhesive,[170] Gianturco coils,[171] and detachable balloons.[172]

LATE RESULTS

This section will mainly consider the long-term results following complete repair of tetralogy of Fallot or tetralogy of Fallot with

pulmonary atresia. Firstly, a brief discussion of the outlook for patients who have not undergone complete repair is warranted. Although survival to adulthood without benefit of surgical palliation or repair has been reported, less than 5% of untreated patients will survive beyond 25 years of age.[173,174] A small group of patients who underwent systemic to pulmonary artery anastomoses during the first decade that these procedures were available did not undergo complete repair when it later became possible. This was generally because these patients had achieved an excellent functional result from their palliative procedure and did not wish to undergo another operation. The majority of these patients eventually required complete repair, usually as a result of increasing symptoms due to progressive hypoxia or right and left ventricular dysfunction. This group certainly demonstrated that survival into adulthood was possible solely with palliative surgery but that complete repair ultimately became necessary.[175]

There are two other groups of patients for whom complete repair may not be possible. One group consists of patients with severe pulmonary artery hypoplasia and either pulmonary stenosis or pulmonary atresia. In these patients, if a systemic to pulmonary artery anastomosis or an outflow tract reconstruction procedure is not successful in alleviating hypoxia or polycythemia, then it is unlikely that these patients will survive into the second or third decade of life. In general, if palliative procedures achieve an adequate result, then the pulmonary arteries are usually of sufficient size to attempt complete repair. The second group consists of those patients who have developed pulmonary vascular disease due to a large systemic to pulmonary artery anastomosis. This was common with the Potts anastomosis and in more recent years following a Waterston shunt.[146–148] Included in this group are patients with tetralogy of Fallot and pulmonary atresia with pulmonary blood flow occurring through large, unrestrictive systemic to pulmonary collateral arteries. These latter two groups have increased pulmonary blood flow as a result of their surgically created or naturally occurring systemic to pulmonary artery connection. This leads to problems related to increased pulmonary blood flow and congestive heart failure rather than decreased pulmonary blood flow and hypoxia. The end result of this large unrestricted pulmonary blood flow is usually the development of pulmonary vascular disease which precludes complete repair. These patients would be expected to survive into the third or fourth decade of life and would ultimately develop problems with hypoxia, polycythemia, and ventricular dysfunction in a manner similar to patients who develop pulmonary vascular disease from other types of congenital heart disease.

In most centers, over 90% of patients who undergo complete repair of tetralogy of Fallot will survive to adulthood and have a good functional long-term result.[149] Since the long-term survival of patients having undergone successful repair of tetralogy of Fallot is very close to the expected survival of an age, race, and sex-matched population,[176] this suggests that most mortality from complete repair of tetralogy of Fallot occurs perioperatively or within the first few years following operation. Although postoperative hemodynamic abnormalities such as residual ventricular septal defects or some degree of right ventricular outflow tract obstruction are often present, these are usually not severe enough to require reoperation and have not yet been demonstrated to affect long-term mortality. Other problems such as pulmonary regurgitation and arrhythmias may also influence the long-term results and survival.

Residual Pulmonary Stenosis

Postoperative right ventricular hypertension is usually due to residual pulmonary stenosis, a residual ventricular septal defect, or both. Pulmonary hypertension secondary to pulmonary vascular disease is uncommon but may be found in patients with a previous systemic to pulmonary artery shunt, particularly the Potts anastomosis. Residual pulmonary stenosis may occur at the level of the pulmonary valve or the annulus and is due to either inadequate relief of obstruction at the time of operation or recurrent valvar stenosis. Residual obstruction may be apparent in the early postoperative period and Kirklin et al. have recommended reoperation for placement of a transannular outflow patch, even as early as 24 hours postoperatively, if right ventricular hypertension of greater than 70 to 80% of systemic level persists.[20] Pulmonary artery stenosis either at the pulmonary artery bifurcation or more distally, is the most common cause of residual right ventricular hypertension. This may occur at the site of distal insertion of a pulmonary artery patch, or at the site of pulmonary artery reconstruction following a systemic to pulmonary artery anastomosis (in particular the Waterston anastomosis). The combination of distal pulmonary artery stenosis and pulmonary regurgitation postoperatively produces both right ventricular volume and pressure overload and may result in considerable right ventricular dysfunction. Thus, if significant pulmonary artery stenosis is anticipated at the time of initial repair or following reoperation, insertion of a valve in the pulmonary position, or the use of a valved conduit, has been recommended.[20]

Some degree of residual pulmonary stenosis is present in most patients who have undergone repair of tetralogy of Fallot.[93,96,149] In about two-thirds of cases this is usually either trivial or mild enough so that right ventricular pressure is less than 50% of systemic level. In approximately another 25% of patients a moderate degree of right ventricular hypertension is present with right ventricular pressure over 50% but less than about 75% of systemic level. In these patients reoperation is usually not required unless a significant residual ventricular septal defect is also present. Residual right ventricular hypertension greater than 75% of systemic level and requiring reoperation occurs in as many as 10% of patients.[177]

Pulmonary Regurgitation

There has been considerable debate over the years about the longterm effect of the pulmonary regurgitation that is produced by pulmonary valvectomy and/or the use of a transannular outflow patch. Unless this occurs in conjunction with significant residual pulmonary stenosis, even wide open pulmonary regurgitation is usually well tolerated and most patients are entirely free of symptoms.[93,96,149] On the other hand patients with pulmonary regurgitation have larger cardiothoracic ratios on chest roentgenogram and larger right ventricular volumes.[178] In addition, incompetence of the pulmonary valve was associated with either reduced exercise capacity or other abnormalities demonstrated at postoperative stress exercise testing.[96] Thus, although almost all of these patients appear to be functionally normal, these abnormalities of right ventricular size and function may be a source of problems over the long term. The question of whether continued pulmonary re-

gurgitation will have a deleterious effect on right ventricular function and ultimately affect long-term survival remains to be answered.

Residual Ventricular Septal Defect

The frequency of small or large residual ventricular septal defect varies, but may be as high as 20% of patients who have undergone repair of tetralogy of Fallot.[93,96,149] This communication may result from dehiscence in a small area of the patch or possibly just excessive space between two sutures. A major dehiscence will result in a large left-to-right shunt and will usually require reoperation. A second or multiple ventricular septal defects also may be present in the trabecular muscular septum in patients with tetralogy of Fallot. Even if this defect is identified preoperatively, it may be covered by trabecular muscle on the right ventricular side of the septum and may be extremely difficult to localize and repair at the time of operation. It is extremely important not only to identify the presence of this additional type of defect, but also to determine its size preoperatively. If this defect is assessed to be small, it will not contribute a large left-to-right shunt in the postoperative period, and the recommendation is made to the surgeon that closure of the defect is not necessary at the time of operation. On the other hand if a large left-to-right shunt is expected because of the size of the defect then an attempt at closure should be made at the time of operation even if it means approaching the defect through the apex of the left ventricle. This latter approach is used only if an extremely large defect is present since the addition of a left ventriculotomy at the time of repair is likely to result in poor cardiac output and bilateral ventricular dysfunction in the postoperative period.

In most patients a residual ventricular septal defect with a pulmonary to systemic flow ratio (Q_p/Q_s) of less than 1.5/1 is well tolerated and reoperation is usually not recommended. If the Q_o/Q_s is greater than 1.5/1 to 2/1, then reoperation is recommended.[149,177] This magnitude of residual shunt will ultimately produce ventricular dysfunction especially if it is present in combination with other problems such as right ventricular hypertension due to residual pulmonary stenosis. Reoperation for a residual ventricular septal defect is usually successful with little additional mortality. It results in improvement in ventricular function and a predicted beneficial effect on long-term survival.

Ventricular Function

Abnormalities of right or left ventricular function may occur as a result of a residual left-to-right shunt, residual pulmonary stenosis, or pulmonary insufficiency.[95,96] These may occur alone or in combination. A residual left-to-right shunt with resultant left ventricular dysfunction and congestive heart failure may occur from a residual ventricular septal defect or a systemic to pulmonary artery anastomosis that was not effectively closed at repair.[179] In addition, large systemic to pulmonary collateral arteries may also produce a similar problem. When large collateral arteries are identified preoperatively some attempt should be made to ligate these vessels at the time of operation. Unfortunately this is often unsuccessful and a number of techniques for occlusion of these vessels in the cardiac catheterization laboratory have been used to avoid reoperation.[170–172] If one of these procedures is not successful in alleviating a large left-to-right shunt, then reoperation through a posterolateral thoracotomy may be necessary to ligate these vessels at their origin from the descending aorta.

Right ventricular dysfunction is usually a result of the combination of volume overload from a residual ventricular septal defect and/or pulmonary regurgitation and pressure overload from residual pulmonary stenosis. The combination of pulmonary regurgitation with or without pulmonary artery stenosis has been discussed in the preceding paragraphs. Even in patients with a good hemodynamic result, right ventricular dysfunction is evident in the early postoperative period with right ventricular end diastolic and mean right atrial pressures usually in the range of 12 to 15 mm Hg or higher.[180] It has been recognized for many years now that a right atrial pressure in the normal range of 5 to 6 mm Hg or less in the first 24 hours following tetralogy of Fallot repair is a sign of hypovolemia and indicates the need for immediate volume expansion. These "normal" elevated right ventricular end diastolic and right atrial pressures are presumed to reflect temporary right ventricular dysfunction. Although these elevated pressures may persist for a few weeks and are often found at cardiac catheterization within 1 month postoperatively, this appears to be a temporary phenomenon since most patients with good ventricular function exhibit normal right ventricular end diastolic and right atrial pressures at catheterization 1 to 2 years postoperatively.[94]

Left ventricular function is also compromised in the early postoperative period and many patients require temporary inotropic support in the first 24 hours.[180] It is common for patients who have had repair of tetralogy of Fallot to receive digoxin therapy postoperatively but this can usually be discontinued within a few months unless the patient has congestive heart failure from residual abnormalities. Left ventricular dysfunction may also be found postoperatively in patients with coronary artery abnormalities. An anomalous or accessory anterior descending coronary artery arising from the right coronary artery and crossing the right ventricular outflow tract is at risk for injury during repair.[31,34] If this arterial anomaly is not recognized preoperatively, a vertical incision in the right ventricular outflow tract will transect that coronary artery especially if it is necessary to extend the incision across the pulmonary valve annulus. A myocardial infarction will then occur in the areas supplied by this coronary artery with resultant postoperative left ventricular dysfunction that persists over the long term. Since little can be done to reverse the damage that occurs due to injury to the coronary artery, it is clearly essential that this problem be recognized preoperatively. When it is present, the repair is performed through a horizontal ventriculotomy or through a transatrial approach and a right ventricle to pulmonary artery conduit is used if the right ventricular outflow obstruction cannot be relieved adequately by infundibular resection and/or pulmonary valvotomy alone.

Arrhythmias and Conduction Abnormalities

Atrioventricular conduction abnormalities are common following repair of tetralogy of Fallot and are infrequent preoperatively (see section on Cardiac Catheterization in this chapter).[107,108] Right bundle branch block results from injury to the right bundle branch but in itself appears to be benign. The appearance of postoperative bifascicular block (left axis deviation with right bundle branch block), especially in a patient who had transient complete AV block at the time of surgery, has been considered a possible warning sign for development of late complete AV block.[72,73] However,

followup in the majority of these patients has been benign. Permanent complete atrioventricular block following repair of tetralogy of Fallot usually necessitates the insertion of a permanent pacemaker. Even if the ventricular rate is rapid, insertion of a pacemaker would definitely be indicated if the atrioventricular block occurs below the level of the bundle of His.[74] Thus, in a postoperative patient, an attempt should be made to determine the site of atrioventricular block by recording His bundle electrograms if it is contemplated *not* to insert a permanent pacemaker.

Fortunately, complete atrioventricular block is now uncommon following repair of tetralogy of Fallot. However, if complete atrioventricular block occurs, especially with a slow idioventricular rhythm, many surgeons would consider insertion of permanent pacing wires at the time of repair. External pacing through temporary ventricular epicardial pacing wires will be sufficient to maintain heart rate during the early postoperative period. If the atrioventricular block does not resolve within 2 weeks, then the permanent pacing wires will already be in place thus enabling a simpler operation for insertion of the permanent pacemaker.

Premature ventricular contractions (PVCs) may be found at rest or may be induced by exercise in patients who have undergone repair of tetralogy of Fallot. In many cases these are benign and have little significance. On the other hand serious ventricular arrhythmias may occur and these include multiform PVCs, ventricular tachycardia, or ventricular fibrillation. Although it was previously felt that sudden death in patients who have undergone repair of tetralogy of Fallot was a manifestation of the late onset of complete heart block,[75] it is currently believed that sudden death is more likely due to serious ventricular arrhythmias.[76,77] A number of investigators have suggested that these arrhythmias are more common in patients with significant residual hemodynamic abnormalities. In most centers stress exercise testing and 24-hour ambulatory monitoring are routinely performed in patients who have undergone repair of tetralogy of Fallot. This is especially true in those patients who are found to have PVCs on routine electrocardiography. Uniform PVCs are probably benign, unless they are extremely frequent. However, more serious ventricular arrhythmias, especially when they are provoked by exercise testing and/or are associated with right ventricular hypertension at greater than 75% of systemic level should probably be treated. In this situation many centers would perform intracardiac electrophysiologic testing and assessment of various modalities of pharmacologic therapy, especially in patients who are symptomatic from their ventricular arrhythmias. Reoperation may be warranted if the cause of the residual right ventricular hypertension is amenable to surgical repair.

Other Long-term Considerations

Numerous followup studies of patients who have undergone tetralogy of Fallot repair have demonstrated that the vast majority of patients are functioning normally and do not consider themselves to be disabled. Most patients feel that they have normal exercise tolerance and exercise capacity has been demonstrated to be in the normal range in over 80% of patients by stress exercise testing.[181,182] Serial exercise testing has demonstrated no deterioration of exercise capacity in the majority of patients. Clearly this varies from one series to the next and is also dependent upon the percentage of patients with significant residual hemodynamic abnormalities that are included in each study.

Complete repair of tetralogy of Fallot eliminates neurologic complications such as brain abscess and cerebrovascular accidents that are possible in preoperative patients with hypoxia, polycythemia, and a right-to-left shunt. Patients who have had complete repair are still susceptible to infectious endocarditis since residual abnormalities are common, even though in most cases they are not hemodynamically significant. Thus, appropriate antibiotic prophylaxis against this problem is recommended for all patients throughout their lives.

The surgical management of tetralogy of Fallot has resulted in the likelihood that over 90% of patients with this lesion will survive to adulthood and lead active, healthy and productive lives. It is impossible to predict what will occur in the future but thus far, patients who have a good hemodynamic result from operations performed more than 30 years ago continue to show no signs of deterioration. The status of right and left function over the long-term are still of concern especially since the effects of coronary artery disease in a heart with a repaired congenital defect are unknown. Lastly, large numbers of patients are entering their child-bearing years and current data would indicate that the incidence of cardiac abnormalities in their offspring may be more than 15 times higher than in the general population. In this group, prenatal diagnosis by means of fetal echocardiography is strongly recommended. It is possible that these patients with repaired tetralogy of Fallot who are now surviving to adulthood will produce a new generation of children in whom the incidence of tetralogy of Fallot is much more frequent than in their parents' generation.

CHAPTER 64

Absent Pulmonary Valve Syndrome

William W Pinsky

Congenital absence of the pulmonary valve leaflets is a relatively rare syndrome. Initial reports were described by Crampton in 1830[1] and Favell in 1842[2] with followup description by Cheevers in 1847[3] when he reported a syndrome of congenital heart defects that included absent pulmonary valve leaflets, ventricular septal defect, annular pulmonary stenosis, and dilatation of the main pulmonary artery and one or both of the pulmonary artery branches. Approximately 2 to 6% of patients described as having tetralogy of Fallot also have absence of the pulmonary valve leaflets.[4,5]

DEFINITION

In the absent pulmonary valve syndrome, there is either a complete absence of pulmonary valve leaflets or an uneven rim of rudimentary tissue found in the area of the pulmonary annulus. There is also stenosis of the annulus and perhaps also obstruction at the level of the infundibulum (Fig. 64–1). In the usual form of the syndrome there is overriding of the aorta, ventricular septal defect, and displacement of the right ventricular outflow tract to the left with an undeveloped infundibulum as seen in tetralogy of Fallot.[6] The most often recognized characteristic of the syndrome is the aneurysmal dilatation of the main pulmonary artery and its branches. There also may be stenosis at the origin of the pulmonary artery branches as well as arborization abnormalities. An uncommon but reported association of absence of the proximal portion of the left pulmonary artery exists,[7–17] and rarely, origin of one pulmonary artery from the ascending aorta.[18]

PHYSIOLOGY

Although the anatomy in the full syndrome is more similar to tetralogy of Fallot, the physiology is a combination of problems associated with left-to-right shunting and airway obstruction.[8,13,19] In early infancy, patients seem to divide themselves into two groups, one group with severe respiratory problems and one group with less severe problems. In the immediate newborn period, many of these patients are cyanotic, independent of their respiratory function. This is most likely because of the relatively high pulmonary resistance with an incompetent pulmonary outflow tract in association with a VSD. Characteristically the cyanosis abates as the pulmonary vascular resistance falls.[8,13]

The intracardiac shunting frequently becomes a net left-to-right shunt. Patients therefore have increased pulmonary blood flow. This increased flow in addition to the native dilatation of the pulmonary arteries may cause significant respiratory difficulties.[8,13] The dilated pulmonary arteries compress the large airway creating a ball-like effect. This effect may be compounded by enlargement of the left atrium, which further compresses particularly the left mainstem bronchus. There also may be intrinsic abnormalities to the integrity of the bronchioles causing further airway obstruction. Rabinovitch[19] thoroughly analyzed the lungs and vascularity in three post mortem patients using morphometric techniques. She found a bizarre pattern of hilar branching in addition to the expected central vascular airway problems. There were tufts that entwined and compressed the intrapulmonary bronchi. In addition, the histologic structure of the pulmonary arteries was abnormal. There were both decreased bronchial generations as well as impaired alveolar multiplication. It was these findings that led to

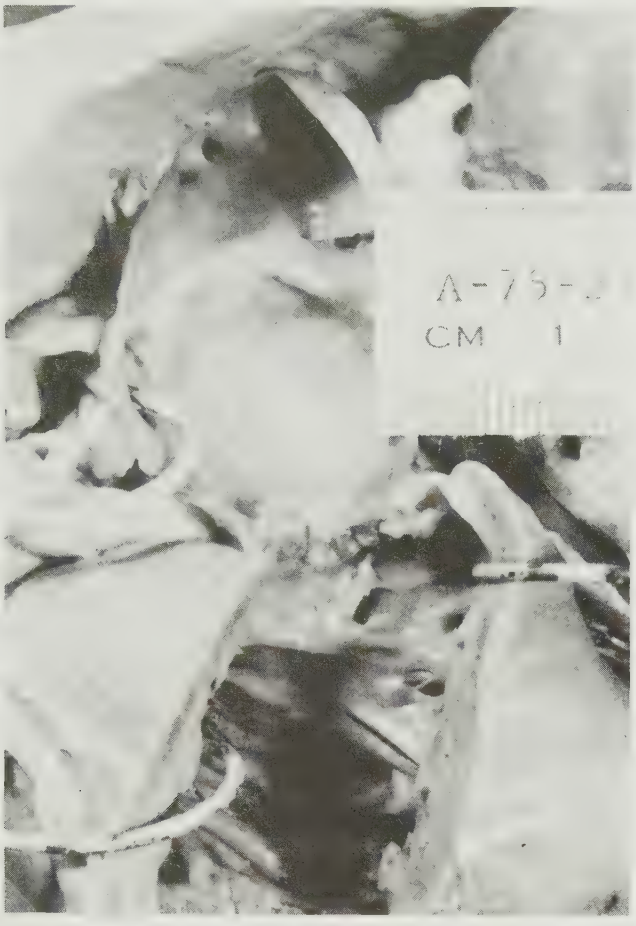

Fig. 64–1. Gross specimen of an infant heart opened from the right ventricular outflow tract into the main pulmonary artery. The hypertrophy of the right ventricle is demonstrated. Remnants of a pulmonary valve can be seen in the area of the pulmonary annulus. The main pulmonary artery is markedly dilated.

Rabinovitch's conclusion that some patients, even with relief of compression of the mainstem bronchi, still persist with severe respiratory dysfunction.

EMBRYOLOGY/FETAL CIRCULATION

The importance of the absence of the ductus arteriosus has been highlighted by Emmanouilides et al.[20] They reported four patients with this syndrome and absence of the ductus arteriosus. They feel there is a pathogenetic relationship between the lack of development of the ductus arteriosus and the pulmonary artery dilatation. It is felt that the lack of presence of the ductus arteriosus early in the fetus' life prevents the main outlet of the right ventricular circulation.[20] This would result in backwards blood flow through the pulmonary artery returning to the right ventricle and then passing to the lower resistance placental circulation from the left ventricle via the ventricular septal defect. Because the annulus is stenotic, poststenotic dilatation may also occur, further exacerbating the enlargement of the pulmonary arteries. This is a likely cause-and-effect relationship since the massive enlargement of the main pulmonary artery and its branches occurs as a prenatal event. There also may be a congenital weakness of the pulmonary arterial walls, although there has been no histologic evidence of this fact.[17,21] The right ventricular stroke volume is increased in utero due to the pulmonary insufficiency as well as the shunting through the ventricular septal defect.

Smith et al.[22] from the Mayo Clinic felt that the ductus was not involved as a primary problem. They hypothesized that in those patients where a ductus arteriosus was present, the aneurysmal dilatation of the pulmonary arteries and enlargement of the right ventricular cavity were exacerbated due to the increase in pulmonary arterial pressure in utero with diastolic runoff by way of the ductus arteriosus into the right side of the heart. This was disputed by Lakier,[8] who felt that the flow would be more prograde through the ductus to the systemic circulation, again because of the lower placental resistance.

The orientation of the right ventricular outflow tract and site of the VSD suggest a similarity with this syndrome and conotruncal maldevelopment as seen in tetralogy of Fallot.[6] In a review of their surgical cases, Calder et al.[18] felt most of the VSDs were consistent with a tetralogy location, however, they did have patients with deficiency in the conal septum that extended to a more anterosuperior direction, which differs from the classical tetralogy of Fallot. However, they felt that the constellation of defects still was very similar to that seen with tetralogy of Fallot.

ASSOCIATED ANOMALIES

Of the over 200 reported cases of absent pulmonary valve,[1–94] there have been only a few patients who had no associated cardiac anomalies.[22,35,46,54,69,75] Other than the tetralogy type of defect, other commonly associated anomalies include secundum atrial septal defect,[22,64,94] hypoplasia of the right ventricle,[46] double outlet right ventricle,[26,40,7,84] tricuspid valve atresia,[2,47,62,76] Marfan's syndrome,[36] endocardial cushion defect,[84] transposition of the great arteries,[19] Uhl's anomaly,[55] and aortic origin of one of the pulmonary arteries,[18,92] Additionally, DiGeorge syndrome[30,78] has been associated with this anomaly.

CLINICAL PRESENTATION

Because of the somewhat unusual constellation of defects and physiologic effects, infants may be referred to the cardiologist because of a heart murmur, cyanosis, "heart failure," respiratory failure or any combination thereof.[13] The murmur of absent pulmonary valve syndrome is unique, and other than aortic stenosis/insufficiency (e.g., aorticoventricular tunnel),[95] in the newborn it should not be confused with any other entity.

There may be cyanosis as a neonate when the pulmonary vascular resistance is relatively high and when there is relatively decreased compliance of the right ventricle decreasing the prograde flow through the pulmonary circulation with resulting right-to-left shunting through the ventricular septal defect. As the pulmonary vascular resistance decreases, then the cyanosis becomes less evident and more of a left-to-right shunt develops. Although many of these patients do not have the development of ductus arteriosus, it is interesting that infusion of PGE_1 may cause improvement in their cyanosis. This most likely is due to the prostaglandin's effect in decreasing vascular resistance[96] as opposed to opening a "nonexistent" ductus arteriosus.

"Congestive heart failure" as evidenced by increased respiratory rate, rales, gallop, and evidence of increased pulmonary blood

flow will manifest itself as the pulmonary resistance drops. Not all patients with this syndrome will have these findings as the pulmonary annular stenosis may restrict enough left-to-right shunting to give a "balanced picture." Patients who do exhibit signs of increased left-to-right shunt may have this shunting decrease as the infundibular stenosis develops over time.

Presentation with significant respiratory insufficiency is frequently the reason for referral. These patients have air trapping secondary to the bronchial and bronchiolar compression from the enlarged aneurysmal pulmonary arteries and pulmonary arterioles as described earlier.[8,13,19] This can be a diffuse process or it can be more segmental. On examination one can find evidence for adequate air intake but expiration is greatly diminished. Lungs become hyperresonant with potential shifting of the cardiac structures.

PHYSICAL EXAMINATION

In patients without severe respiratory involvement there will be minimal cyanosis.[13] The degree of overriding of the aorta and amount of annular stenosis are significant determinants in the degree of cyanosis. In practicality, the annular stenosis and infundibular hypertrophy generally are not as severe as in the standard tetralogy of Fallot; therefore the patient's cyanosis is less prominent in this syndrome. The chest examination should be unremarkable except for perhaps slightly increased resonance. Breath sounds should be unremarkable. The precordial examination will demonstrate an active right ventricular impulse at the left lower sternal border commensurate with the degree of right ventricular volume and pressure overload. Depending on the degree of left-to-right shunting, the left ventricular impulse may have increased activity although the apex is generally not displaced. The first heart sound is normal and the second will be single and increased. There is a high-pitched systolic ejection murmur, secondary to the annular and infundibular stenosis, that is maximally located at the third left intercostal space although it will radiate through the pulmonary distribution, that is, to the right chest anteriorly and to both sides of the back. A typical low-pitched decrescendo diastolic murmur of pulmonary valve insufficiency will be heard in the third left intercostal space. This creates the typical to-and-fro murmur of this entity.[97]

In patients with severe bronchial compression, their cyanosis is more dependent upon the degree of respiratory distress.[8,13,19] These patients may have a significant amount of air hunger secondary to trapping. Although the pCO_2 will increase first, there can be a significant decrease in the pO_2 as respiratory failure progresses. There is generally hyperinflation with increased resonance on percussion of the chest, which can be diffuse or segmental depending upon the distribution of involvement. Breath sound alteration will track the degree of lung involvement. The cardiac findings will be similar to that found in patients without significant respiratory problems.

NONINVASIVE TESTING

Chest radiographs indicate a range from a normal to mildly enlarged cardiac silhouette. Enlargement of the cardiac silhouette is generally due to enlargement of the right ventricle. Typically there is marked dilatation of the main pulmonary artery as seen on chest radiograph with prominence of the pulmonary artery branches seen centrally. Depending upon the amount of left-to-right shunting, the left mainstem bronchus may be upturned as the left atrium enlarges.[8] Relative to the amount of respiratory involvement, there is hyperinflation secondary to bronchial obstruction (Fig. 64–2). In severe forms of air trapping, there may actually be herniation of a lobe. This may result in mediastinal shift. One should note the position of the trachea to help in identifying a right-sided aortic arch, found in this syndrome similar to some patients with tetralogy of Fallot.

The electrocardiogram typically demonstrates right axis deviation and right ventricular hypertrophy secondary to both right ventricular pressure and volume overload states. There may be associated left ventricular hypertrophy in those individuals with significant right-to-left shunting. There also may be right atrial enlargement usually on the basis of decreased right ventricular compliance.

Echocardiography can be diagnostic for this syndrome. As suggested by Cheatham et al.[34] and further described by de Albuquerque et al.,[85] in addition to the overriding large posterior great artery with subaortic ventricular septal defect, the right ventricular outflow tract will be patent and a narrow pulmonary annulus noted. The pulmonary valve will be poorly visualized.[66] The main pulmonary artery will be identified as quite enlarged as will one or both of the branches. There will be evidence of right ventricular volume overload by an enlarged right ventricle and paradoxical septal motion. Doppler interrogation will demonstrate turbulent flow across the right ventricular outflow tract with a significant

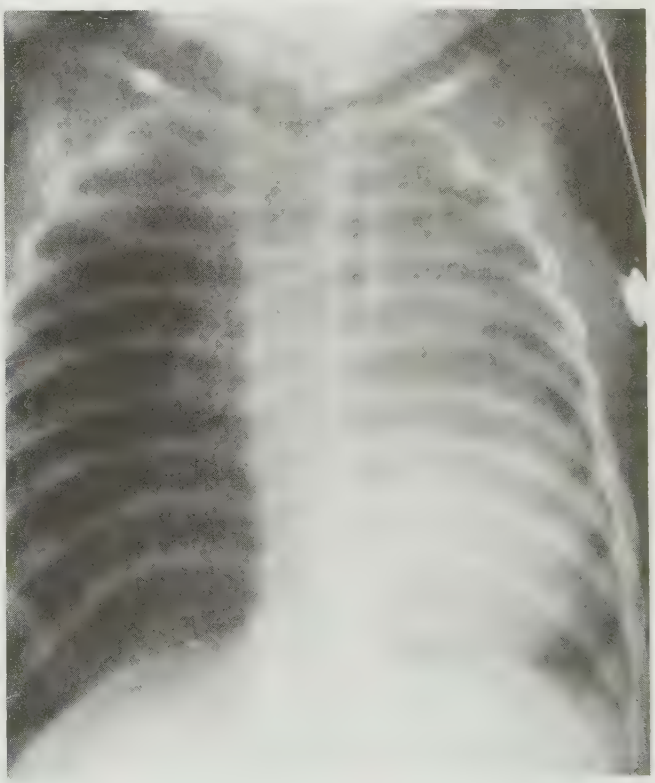

Fig. 64–2. AP chest roentgenogram of an infant. Note flattening of the diaphragms indicative of the hyperinflation secondary to air trapping.

gradient calculated. In addition, pulmonary insufficiency is displayed by diastolic flow through the pulmonary artery back into the right ventricular outflow tract. An important observation is that ductus arteriosus flow will not be identified. Obviously those instances where the absent pulmonary valve is in association with other intracardiac type of defects, those findings will be present in addition to the Doppler findings of pulmonary insufficiency and right-sided enlargement.

INVASIVE TESTING

In patients with the usual syndrome, there is equalization of the pressures between the ventricles due to the large ventricular septal defect. The gradient across the RV outflow tract will depend upon the amount of narrowing in the infundibular and annular areas. The diastolic pressure in the pulmonary artery approaches zero indicating the lack of restriction of flow back into the right ventricle due to severe pulmonary insufficiency. There may be a gradient to either pulmonary branch depending upon stenosis of those areas. Even with a left-to-right shunt, the pulmonary vascular resistance is generally normal. Increased right atrial pressure indicates some loss of compliance of the right ventricle due to its volume and pressure overload states. Left ventricular end diastolic pressure and atrial pressure will reflect the increased degree of left-to-right shunting as the QP/QS increases. Oxygen saturations indicate a normal mixed venous oxygen saturation with a step up in saturation in the right ventricle and pulmonary arteries. Depending upon the degree of override of the aorta, there may be some arterial desaturation as well. Right ventricular angiography reveals the typical "Mickey Mouse ears" appearance of the dilated main pulmonary artery and its branches (Fig. 64–3). The right ventricular injection utilizing cranial oblique views visualizes the origin of the pulmonary arteries and their distribution to rule out any localized areas of stenosis. Also, the degree of right-to-left shunting can be identified angiographically. A contrast injection in the main pulmonary artery will characterize the degree of pulmonary insufficiency, as well as delineate areas of vascular crowding secondary to air trapping. Left ventricular angiography, again using cranial oblique views, delineates the exact site of the defect in the ventricular septum. In the usual syndrome, there are not multiple ventricular defects; however, variations can be expected. Because of the concern for coronary artery distribution abnormalities in those with tetralogy of Fallot, it is important to identify the course particularly of the left anterior descending coronary artery before planning intracardiac repair.

NATURAL HISTORY

Those patients with severe bronchial obstruction will develop respiratory symptoms, sometimes as early as the early neonatal period.[13,20,27,41,53,54,61,91] In other cases, symptoms may develop later in the first month of life. Generally these symptoms are exacerbated by any type of respiratory infection. As in other forms of congenital heart disease, infection with respiratory syncytial virus can be very serious. Frequently the respiratory symptoms will overshadow the cardiac problems from the left-to-right shunt. As the airways increase in size and integrity, the respiratory symptoms will tend to regress. However, this cannot be expected until at the earliest 6 to 9 months of age. Frequently the respiratory status will stabilize after age 1.[8,13] These patients may have significant growth failure secondary to decreased caloric intake as well as caloric usage primarily on the basis of their respiratory failure.

Those patients with less severe bronchial compression act more like a patient with "pink tetralogy of Fallot." Different from

Fig. 64–3. Right ventricular angiogram in a cranial/LAO position. This demonstrates a narrowed annulus. There is marked dilatation of the main pulmonary artery and its branches.

patients with tetralogy of Fallot who have increasing cyanosis with age,[98] these patients do not become more cyanotic. They may have some "heart failure" with related symptoms. Their respiratory symptoms are mild at most and only require treatment in unusual circumstances. As in other patients with significant left-to-right shunts, they also may have growth failure.

THERAPEUTIC APPROACH

In patients with severe bronchial obstruction their medical treatment needs to be directed toward their respiratory function.[25,13] Specific therapy to improve ventilatory function should be much more effective in relieving symptoms in this group than anticongestive measures. It is sometimes necessary to mechanically ventilate those infants who develop respiratory acidosis with significant hypercarbia. However, it is important to ventilate these patients only in extreme instances and with minimal settings. Once one makes such a patient ventilator dependent with positive pressure, it is very difficult to wean from the support. Continually pumping air into the lungs without adequate expiration may only exacerbate the air trapping. A respiratory therapy program in the hospital including nebulization of agents to reduce secretions and dilate the airway frequently can be successful. Treatment of any ongoing respiratory infections likewise is necessary. Arensman et al.[25] described successful experience of positioning patients with severe respiratory problems in a semiprone position (patient lying with head elevated) to maintain their airway patency. Utilizing a type of "Herbst board," they found their patients could be treated successfully medically. They recommend this type of approach because of the reported high surgical mortality in young infants with this syndrome and respiratory distress.

Patients with more minor symptoms will also benefit by a preventive respiratory program. This would include early treatment of respiratory infections sometimes even necessitating a home inhalation program as is used with patients with chronic asthma or cystic fibrosis. The symptoms of left-to-right shunting should be treated in the usual manner with decongestive measures and nutritional support.

There is no uniform consensus to the surgical approach to these patients.[19] Patients with this syndrome have undergone palliative plication of the aneurysmal pulmonary arteries in infancy to help relieve the symptoms.[23,25,41,61,62,77] However, these patients frequently continue to have respiratory distress even after this procedure is accomplished. This may be due to the abnormality of the pulmonary arterioles as suggested previously by Rabinovitch.[19] Certainly, plication without repair of the intracardiac defects has not been very successful.[19] Other individuals have suggested banding of the main pulmonary artery to reduce pulmonary arterial flow thus decompressing the pulmonary artery circulation and left atrium.[68,70] An extension of this technique would be to ligate the main pulmonary artery and then perform a systemic arterial to pulmonary artery anastomosis.[29,53] Patients would then have further intracardiac repair at a later time. Some continue to stress the need for "aggressive" medical therapy and surgical therapy during infancy only when forced because of poor progress of the respiratory situation.[25,13]

Further controversy exists whether it is necessary to insert a prosthetic valve in the pulmonary location. We[13] reported a series where prosthetic pulmonary valves were not inserted and appeared to have good long-term outcome. This included two patients who went on to carry pregnancies successfully to term. Others feel that insertion of a prosthetic valve will lower the volume overload state to the right side of the heart thus reducing the pulmonary artery dilatation.[18,41,52,60,63] Although this is theoretical, this has not been demonstrated to be a necessary cause-and-effect relationship. The insertion of a prosthetic valve adds to the risk of surgery and long-term to the potential complications with mechanical valves and bioprostheses.

OUTLOOK

Patients who have undergone successful intracardiac repair generally have an improvement in their respiratory situation so that does not continue to be a limiting factor in their life. However, one should be aware that successful anatomic repair does not dictate relief of respiratory symptoms in the early postoperative period. In the patients with the usual syndrome, their long-term outlook should be similar to patients with tetralogy of Fallot who have had intracardiac repair and have pulmonary valve insufficiency. These patients, similar to the postoperative tetralogy, need to be observed for the development of arrhythmias and ventricular dysfunction.

CHAPTER 65

Pulmonary Valve Atresia with Intact Ventricular Septum

Donald A Riopel

Pulmonary valve atresia with intact ventricular septum (PA-IVS), also known as pulmonary valve atresia with normal aortic root, is a lesion that consists of varying degrees of hypoplasia of the right ventricle and tricuspid valve. Early writers on the subject were Hunter,[1] Lordat,[2] Hare,[3] and von Rokitansky.[4] The clinical course of very severe hypoplasia of the right ventricle can be almost as devastating as that of severe hypoplasia of the left heart. Although a simple surgical procedure in the neonatal period may save patients with severe hypoplasia of the right ventricle, many such infants die in the first year of life from complications. On the other hand, infants with moderate or mild hypoplasia have a more favorable clinical course. There has not always been unanimity among clinicians about the proper timing and sequence of medical and surgical procedures for this defect, but a common approach appears to be evolving. Possibilities using autogenous muscle are being investigated for the future.

INCIDENCE

The defect accounts for 1 to 3% of cardiac lesions.[5–7] It is estimated to occur in 0.1 to 0.4 per 10,000 births.[8] No distinct sexual preference occurs, although the defect is stated to occur slightly more in boys. A clustering of cases has been reported.[9]

ETIOLOGY

Pulmonary valve atresia can be viewed as the most severe form of valvar pulmonary stenosis. The embryologic origin of the defect has been difficult to demonstrate or to reproduce. At stage 15 of embryological development, four mounds of endocardial cushion tissue are present in the outflow channel of the developing heart tube. There are two large lateral cushions and two smaller cushions in the anterior and posterior positions. Each of the larger lateral cushions is subdivided to form two juxtaposed cusps, one in the pulmonary artery and the other in the aorta. These juxtaposed cusps result in the eventual formation of the thin aortic and pulmonary valve cusps.[10] Embryologic maldevelopment of the endocardial cushions should result in abnormalities of both semilunar valves. However, the presence of abnormalities in one valve without abnormalities in the other semilunar valve suggests that the etiology occurs after the valve cusps have formed.[11] Developmental abnormalities in this area of the conal septum would theoretically also result in deficiencies of the ventricular septum, which usually do not exist in isolated valvar pulmonary stenosis or atresia.[12] Kutsche and Van Mierop[13] postulate that in PA-IVS, atresia of the pulmonary valve very likely occurs sometime after cardiac septation has been completed. The majority of the cases have well-developed fused pulmonary cusps with the typical triradiate appearance. The pulmonary artery diameter is almost normal in size in PA-IVS,[14] while in pulmonary atresia with ventricular septal defect (PA-VSD) the pulmonary arteries are generally small and underdeveloped.[13] The patent ductus arteriosus has a more normal structure and horizontal course in patients with PA-IVS, while it is sigmoid, tortuous, and with a downward course in PA-VSD.[13,15] These findings suggest that in fetuses with PA-IVS, there is at one time normal fetal blood flow from the pulmonary outflow tract through the pulmonary artery and ductus arteriosus to the descending aorta, while in PA-VSD, the direction of blood flow is always reversed through the ductus, suggesting

earlier atresia of pulmonary outflow. A fetal inflammatory process has long been proposed as a cause of pulmonary stenosis or atresia with intact ventricular septum.[16–19] The association of pulmonary artery obstruction with rubella infections[20] serves to bolster this hypothesis.

PATHOLOGY

Edwards and associates[21] describe the condition as one that consists of (1) complete obstruction of the pulmonary valve, (2) two distinct ventricles, and (3) a patent tricuspid orifice guarded by a valve. The pathological anatomy of PA-IVS is also well described in series published by Greenwold and associates,[22] Davignon and associates,[23] Freedom and associates,[5,24] Zuberbuhler and Anderson,[14] Bull and associates,[25] and Kutsche and van Mierop.[13]

The pulmonary valve tissue is a membrane, in most cases with fused commissures depicted by raphae and with three formed cusps. The valve was described thus in 60 of the 75 cases reported by Freedom and Keith.[5] In that series, only two valves were bicuspid, and in three instances no valve tissue was present. In Zuberbuhler and Anderson's[14] series, three cases had no pulmonary valve leaflets; in the remaining 23 cases, two types of atretic pulmonary valves were noted. Both types had commissural ridges. In one type, the ridges met in the center (a feature usually associated with severe infundibular atresia), while in the other type, the ridges were present only at the periphery of the membranous pulmonary valve with the center bulging and smooth. In only one case was the pulmonary valve bicuspid, and in one it was quadricuspid. In the series reported by Kutsche and van Mierop,[13] 15 of 20 specimens had three fused cusps.

All series reported a slightly reduced but well-formed, near-normal-sized pulmonary annulus and main pulmonary artery, indicating the probable presence of normal intrauterine blood flow through these structures and the ductus arteriosus, since the ductus had more normal anatomy (supra vidae).

The right ventricular cavity varies in size from tiny to larger than normal, although it is smaller than normal in the majority of cases. In 1956, Greenwold and associates[22] reported 12 cases of PA-IVS; six of the patients had a tiny ventricle, and six had a large ventricle. Differences in electrographic and radiographic patterns were emphasized. Although all patients died, Greenwold and his colleagues concluded that perhaps patients with larger ventricular cavities might benefit from surgery. In 1961, Davignon and associates[23] examined 20 cases of PA-IVS and classified them into two types depending on the size of the ventricle. Type I was described as having a tiny right ventricular cavity, and Type II as having a normal-sized or large right ventricular cavity. However, most published reports emphasize that there is a continuum of right ventricular cavity size. Freedom and colleagues' review of 60 cases[24] classified the right ventricle as markedly underdeveloped in 40%, moderately underdeveloped in 30%, mildly underdeveloped in 10%, normal in 6.5%, and enlarged in 13%. As surgical results were reported, it seemed that some right ventricular cavities could become larger after surgery, a finding that prompted a revised classification of the right ventricle by Bull and associates.[25] This classification was based on the tripartite approach of Goor and Lillehei,[26] who defined a sinus (inlet) portion, incorporating the tricuspid valve apparatus, a trabecular portion lying beyond the insertion of the papillary muscles of the tricuspid valve toward the apex, and a conus (infundibulum) leading to the pulmonary valve. In the report by Bull and associates, all cases of PA-IVS had an inlet portion of the right ventricle, since by definition the tricuspid valve is patent in all of them. Some cases had no trabecular cavity, while others lacked both infundibular and trabecular portions. No patient lacked only an infundibular portion. These authors postulate that variations in muscular hypertrophy rather than hypoplasia account for the presence or absence of various parts of the right ventricle and for the differences in cavity size. The tripartite classification allowed de Leval and colleagues[27] to plan their approach to surgical therapy and to predict prognosis. Arom and Edwards[28] examined the hearts from 18 infants with PA-IVS, paying particular attention to certain muscle bundles of the infundibulum. They felt that specific muscle bundles were consistently related to certain pulmonary valve cusps and that severe hypertrophy of these muscle bundles could completely obliterate the infundibular portion of the right ventricle, isolating the pulmonary valve membrane from the sinus of the ventricle. They concluded that in some ventricles with a narrow infundibulum, only the anterior pulmonary cusp was the part of the membrane in continuity with the infundibulum and that valvotomy should be performed through this portion only.

In 1926, Grant[29] described a case of pulmonary atresia in which there were communications between the ventricle and the coronary artery system via myocardial sinusoids. Since then, several authors have described these unique channels morphologically[23,30–32] and angiographically.[33] Sinusoids have also occurred in some cases of left ventricular outflow obstruction.[34,35] The sponge-like musculature of the embryologic heart muscle is supplied with blood from the intertrabecular spaces and sinusoids. Later, coronary veins develop and communicate with the sinusoids. The coronary arteries develop later and anastomose with the veins. As the myocardium becomes more muscular, the venous communications with the cavity of the ventricles become atretic. At the time of pulmonary valve development, the blood supply to the heart is still derived from its lumen, and if the valve does not develop normally, the elevated pressure in the right ventricular cavity may keep open the sinusoids and venous communications will persist. These fistulous communications seem to be most prominent with small hypertensive right ventricles, occurring in 8 to 55% of reported cases.[36,37] The flow through the coronary arteries can be retrograde (toward the aorta) or bidirectional.[38] Communications are more often with the left anterior descending and left coronary artery than with the right coronary artery. These sinusoids provide an egress of blood from the right ventricular cavity, where forward flow is not possible. Lenox and Friner report a case in which the proximal connections between the aorta and coronary arteries were absent.[39] The coronary arteries undergo a variety of changes resulting in beading, nodularity, and endarteritis, compromising oxygen transport and leading to ischemia of the myocardium.[37] Fibroelastic changes often occur in the right ventricular endocardium, especially at the orifices of the sinusoids.[35]

The tricuspid valve, by definition, is patent in all cases of PA-IVS. Davignon and associates[23] described the valve to be smallest in his type I defects, those with the smallest right ventricles. In the type II defects, the valve was larger, and there was evidence of valvar incompetence. The relationship of the size of tricuspid valve to right ventricle has also been described in other case re-

views.[5,14,24,40] The size of the tricuspid orifice and valve ring appears to be proportional to the size of the right ventricular cavity, although some exceptions were found.[14] In general, the tricupsid valve annulus and orifice tend to be small, and the leaflets tend to be dysplastic, sometimes resembling Ebstein's malformation. The leaflet margins are often rolled and thickened and sometimes attached directly to the small papillary muscles with no intervening chordae. The deformity of the tricuspid valve results in varying severity of stenosis or insufficiency. The size of the tricuspid valve is important in the prognosis of this defect and will be discussed later in this chapter.

The right atrium varies in size depending on the degree of tricuspid insufficiency or stenosis and also depending on the presence of a communication between the right and left atrium. A markedly dilated foramen ovale provides a communication between the right and left atria in most cases, a true secundum defect being present in only 20% of cases.[41] No cases of ostium primum defects in PA-IVS have been reported,[34] but bulging of the primum portion of the atrial septum can obstruct the mitral valve.[42] Severe restriction of the atrial septal communication may be present in 5 to 10% of cases.[34]

Pulmonary veins, the left atrium, and the mitral valve are usually normal. The left ventricle is dilated and hypertrophied. The aortic valve also is usually normal, but some cases of aortic valve stenosis have been described.[43] The aortic arch is left-sided when situs solitus is present.

PHYSIOLOGY

Fetal

With no outlet of the right ventricle, in the fetus with PA-IVS, all systemic venous blood is directed to the left side of the heart through a communication in the atrial septum. Therefore blood flow through the left atrium, mitral orifice, left ventricle, aortic orifice, ascending aorta, and aortic isthmus is increased in comparison to that of the normal fetus. In fact, the total cardiac output must be carried by the left heart, whereas only about 33% of the output is normally carried by the left side.[44] This results in a larger than usual left heart, a larger ascending aorta, and a normal or large aortic isthmus. Flow through the ductus arteriosus is reversed and carries only 8 to 10% of cardiac output, while in the normal fetus, 55 to 60% of cardiac output flows through this structure from main pulmonary artery to descending aorta. As was previously mentioned, the ductus arteriosus in PA-IVS is horizontal and fairly large, suggesting early normal fetal flow through it before the pulmonary valve becomes atretic.

Postnatal

Systemic venous blood enters the right atrium from the vena cavae, and some enters the right ventricle through the patent tricuspid valve; the actual amount depends on the size of the valve and the right ventricle. With no exit possible through the pulmonary valve, the blood must be returned to the right atrium through an insufficient tricupsid valve. Eventually, almost all the systemic venous blood must cross the atrial septum through the foramen ovale or atrial septal defect. Since the communication between atria is necessary before birth, it is usually adequate after birth but may become inadequate several weeks or months later when pulmonary blood flow is better established. In the left atrium, all systemic venous blood mixes with pulmonary venous blood, and systemic arterial blood oxygen saturations depend on the amount of pulmonary blood flow, which in turn depends on the size and patency of the ductus arteriosus. As the ductus undergoes a natural tendency to close, oxygen tension decreases and symptoms of hypoxia occur.

Coronary blood flow through the right ventricular myocardium, even in infants without sinusoid communications, is abnormal. In normal children, blood flows through the right coronary artery system during both systole and diastole, since right ventricular pressures are low throughout the cardiac cycle. However, in infants with PA-IVS, the extremely high pressure in the right ventricle reduces coronary flow, which results in chronic ischemic changes especially in the subendothelial layers and may account for the subendocardial fibrosis of the right ventricle seen in many of these patients.

With the presence of communications between the coronary artery system and the right ventricle via right ventricular sinusoids an intracardiac right-sided circular shunt is formed,[31] which allows venous blood to return to the right atrium without passing through the systemic capillary bed. The pathway of the shunt is from right ventricle to intramyocardial sinusoid, coronary artery, coronary vein, coronary sinus (or thebesian vein), right atrium, and again to right ventricle. The abnormal physiology affects left coronary blood flow and is clinically important when surgery is contemplated.[32]

CLINICAL PRESENTATION

Most infants presenting with PA-IVS are born of a term gestation, have not had growth retardation in utero, and are vigorous. Signs of cyanosis occur variably from a few hours to several days after birth and depend on ductal flow. The cyanosis may be intermittent and associated only with the stress of feedings or may be sudden and severe because of sudden closure of the ductus arteriosus. Infants with very severe cyanosis also have accompanying acidemia and deep compensatory respirations in an attempt to correct the metabolic acidemia. The type of respirations are those of hyperpnea rather than the labored respirations of the infant with the respiratory distress syndrome. Hypoxemia, acidemia, or hypoglycemia can, singly or in combination, lead to seizure activity.

In the symptomatic infant, there is deep cyanosis of the mucous membranes and nailbeds with paleness of the skin secondary to a decrease in cardiac output and peripheral vasoconstriction. The point of maximal impulse is prominent and is located substernally. Hyperpnea is present, and on auscultation of the lungs, no rales are heard. Cardiac auscultation may reveal only the single second heart sound of aortic closure with no murmur, especially if the right ventricle is very small and there is no significant tricuspid insufficiency. If the right ventricle is normal or large in size and there is tricuspid insufficiency, then a long systolic murmur is heard along the lower left sternal border, often with diastolic filling sounds. Rarely is a continuous murmur heard. The liver may be engorged and pulsatile because of passive congestion. Pulses may be diminished.

LABORATORY FINDINGS

Electrocardiogram

The electrocardiographic (ECG) findings of PA-IVS vary depending on the anatomy of the defect and are well described in several series.[45–49] The rhythm is sinus with normal ECG intervals. The P wave is slightly peaked in cases of small right ventricle with little or no tricuspid insufficiency but tall and peaked in cases with considerable tricuspid insufficiency. The P-wave frontal plane axis is normal. The QRS frontal plane axis tends to be in the lower left quadrant or up to $+120°$ in cases of small right ventricle, while it is usually very rightward (greater than $+120°$) in cases with normal or large right ventricles. In severely hypoplastic right ventricles, the R/S ratio in the horizontal plane favors the posterior forces, a finding that suggests absent or diminished right ventricular forces (Fig. 65–1). With a large right ventricle, anterior forces predominate, and criteria for right ventricular hypertrophy are fulfilled. The T wave is usually normal except in cases in which there is ischemia of either the right or left ventricle, in which case discordant T waves are seen, and ST changes of strain are present.

Radiologic Findings

Chest roentgenograms in PA-IVS vary with the anatomic type.[5,50,51] In cases with a tiny right ventricle and little or no tricuspid insufficiency, the heart is normal in size. The main pulmonary artery segment may be deficient or normal, and the overall silhouette may be surprisingly normal. The vascularity is reduced or normal, depending on the patency of the ductus arteriosus. The aortic arch is leftward; a right arch is more often associated with PA-VSD. In cases in which the right ventricle is normal or large with tricuspid insufficiency, the overall heart size is increased, and the enlarged right atrium gives considerable convexity to the right heart border. Since tricuspid insufficiency has been occurring in utero, the right atrium can be huge at birth with an immense cardiac silhouette resembling that of Ebstein's anomaly.

Echocardiography

Although cardiac catheterization and angiography are the most definitive methods of evaluating the anatomy and physiology of PA-IVS, modern echocardiography approaches the same degree of exactness by a noninvasive method. M-mode evaluation of this defect[52,53] has been largely surpassed by the use of two-dimensional standard and color Doppler.[54–56] Four-chambered views allow visualization of the relative sizes of the ventricles and atria (Fig. 65–2a). The presence and size of an atrial septal opening can be visualized and measured. Bulging of the atrial septum into the left atrium should indicate a restrictive opening in the septum.[42] The patency and size of the tricuspid valve will be clearly seen, and function of the ventricles can be evaluated. In short-axis views, the pulmonary valve membrane can be seen as well as the size of the valve ring. The size of the main pulmonary artery and the distance of the proximal main pulmonary artery from the distal right ventricular outflow tract is measurable. Color Doppler echocardiography will show the presence and degree of tricuspid insufficiency (Fig. 65–2b). The right-to-left shunt across the atrial septum and the flow into the main pulmonary artery through the ductus can also be appreciated by color Doppler. Following the surgical relief of pulmonary atresia, the flow and pressure gradient across the pulmonary orifice and right ventricular pressure can be estimated by continuous-wave Doppler.

Cardiac Catheterization

The diagnosis of hypoplasia of the right heart is made from use of the previously mentioned laboratory tools, especially ultrasound. However, cardiac catheterization and angiography remain necessary for visualizing all the details of the anatomy, measuring pressures, and performing necessary interventional procedures. Since many of these infants require balloon septostomy,[57] it can be performed in the newborn period without the use of transseptal equipment or blade catheters. Sinusoidal communications with the coronary artery system are best evaluted by angiography.

The use of prostaglandin E_1 to dilate the ductus arteriosus[58] and

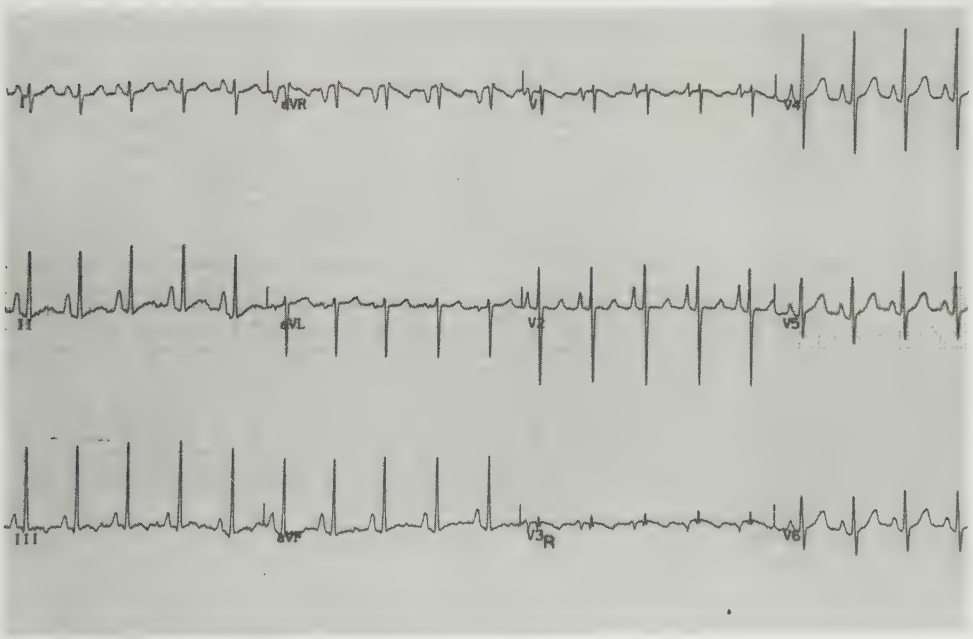

Fig. 65–1 Twelve-lead electrocardiogram of a neonate with PA-IVS and small right ventricle. Note the tall, peaked P waves in lead II and decreased anterior forces in lead V_1.

Fig. 65–2. (a) Two-dimensional echocardiogram in four-chambered view showing the very small right ventricular cavity and severe hypertrophy of right ventricular muscle. (b) Color Doppler echocardiogram showing severe tricuspid insufficiency in the same child.

maintain pulmonary blood flow in these infants has greatly enhanced the safety of catheterization. The infant will change from blue, pale, and acidemic to pink and well perfused within minutes of starting an infusion of prostaglandin E_1 at the rate of 0.05 to 0.1 μg/kg/min. Lower doses may be used with good results. The infusion is effective when given through any vessel including peripheral veins, umbilical vein, or artery. The improved state is maintained as long as the prostaglandin is being infused. Because of possible side effects from prostaglandin such as apnea, seizures, rash, and fever, the infusion should not be prolonged unnecessarily. Prostaglandin will allow cardiac catheterization to proceed less hurriedly at a more opportune time and will also allow some time for the infant to recover from the catheterization before surgery.

Usually, only a venous catheter is necessary for catheterization. Since most infants will have an umbilical artery monitoring catheter, the femoral artery rarely has to be violated. The venous catheter course will be from inferior vena cava to right atrium and thence to the right ventricle. Because of hypoplasia of the tricuspid orifice, the right ventricle may be difficult to enter, and the infant may be thought to have tricuspid atresia. An angiogram in the right atrium will differentiate this, but with prior echocardiography this differentiation should not be necessary. The pulmonary artery is not accessible from the right ventricle. The left atrium is entered through a patent foramen ovale or atrial septal defect. Manipulation into the left ventricle from the left atrium is possible with the use of either a balloon-directed catheter or a J-wire through an end-hole catheter or with the use of a tip deflector inside a closed-tipped angiographic catheter. Hemodynamic data have been summarized in a number of publications.[5,46,47,51] Right atrial pressures are elevated with tall A waves of 15 to 20 mm Hg and mean pressures of 3 to 18 mm Hg (Fig. 65–3). Left atrial pressures are lower by 2 to 3 mm Hg. Right ventricular systolic pressure in those patients with a small right ventricle and very little tricuspid insufficiency have suprasystemic values with a peaked configuration of the pressure curve (Fig. 65–4). Right ventricular systolic pressures may achieve levels of 200 mm Hg but are usually between 100 and 150 mm Hg. Right ventricular end-diastolic pressures will also be elevated, equal to right atrial levels. In those right ventricular chambers with diminished contractility, the systolic pressures can be quite low. The pressures may also be normal

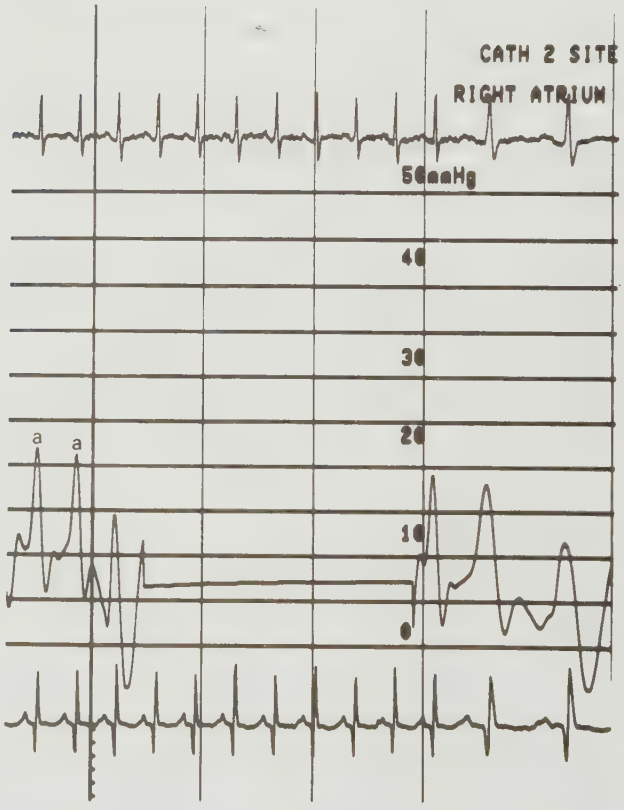

Fig. 65–3. Right atrial pressure tracing from a neonate with PA-IVS showing tall A waves and elevated right atrial pressures.

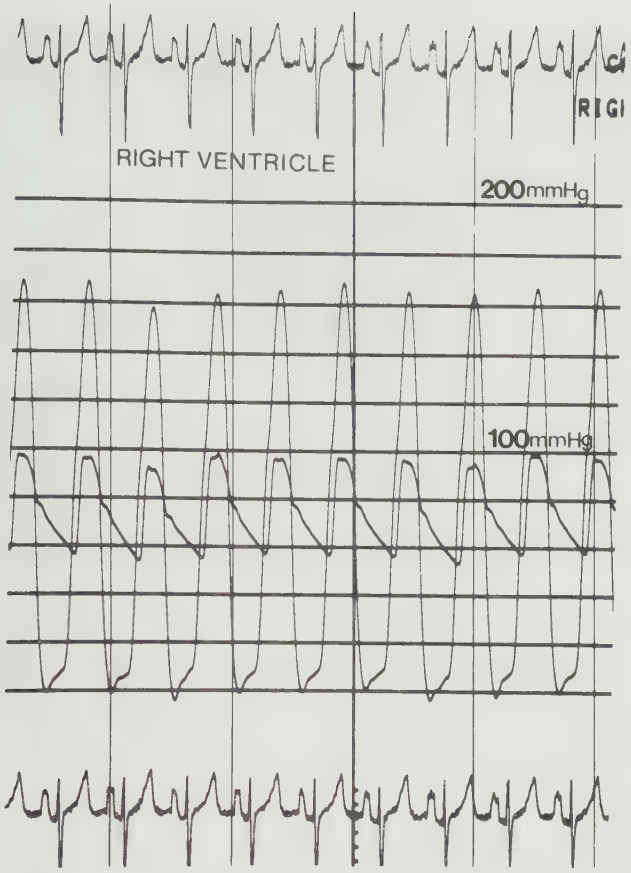

Fig. 65–4. Right ventricular pressures with simultaneous aortic pressures in a neonate with PA-IVS. The right ventricular pressures are peaked and suprasystemic.

or low in cases with large right ventricles and tricuspid insufficiency. Left ventricular pressures usually have normal newborn values unless there is severe hypoxemia, acidemia, and hypoglycemia, all of which decrease contractility and result in low systolic and high end-diastolic pressures. Oxygen saturations are invariably very low in infants who are not being given prostaglandins. Caval and right atrial saturations are often below 30%. Pulmonary venous saturations should be normal. Left atrial saturations are variable because of streaming, and left ventricular saturations reflect arterial saturations that are decreased to an average of about 44%. Because of the large intracardiac right-to-left shunt, administration of oxygen increases systemic saturations very little if any. Arterial blood gases in infants not on prostaglandins will have a low pH, a very low pO_2, often below 20 mm Hg, and a pCO_2 that is somewhat low with a negative base excess. In infants who are receiving prostaglandins, the saturations in all chambers might be surprisingly near normal with very little systemic desaturation. Arterial blood gases in these infants might also approach normal values.

Balloon septostomy should be performed before the end of the catheterization to ensure a good communication between the atria.

Angiography

The preferred locations for angiography are in the right ventricle and in the left ventricle or aorta. An injection in the right ventricle will establish the diagnosis, will show the size of the right ventricle, and will allow classification into the standard type I or II of Greenwold and associates[22] or into the tripartite classification of Bull and associates.[25] Communications with the coronary artery system via myocardial sinusoids may be demonstrated (Fig. 65–5), as well as the degree of tricuspid hypoplasia and insufficiency (Fig. 65–6). Right ventricular volumes are estimated angiographically,[36,59,60] and tricuspid annular size is measured[61] (Fig. 65–7); both are used clinically to plan surgical procedures. Differentiation between functional and structural pulmonary atresia is accomplished during aortography by the observation of pulmonary insufficiency in cases of functional atresia.[62] An important factor in predicting the possibility of establishing continuity between the right ventricle and pulmonary artery is the distance between the distal right ventricular outflow tract and the proximal

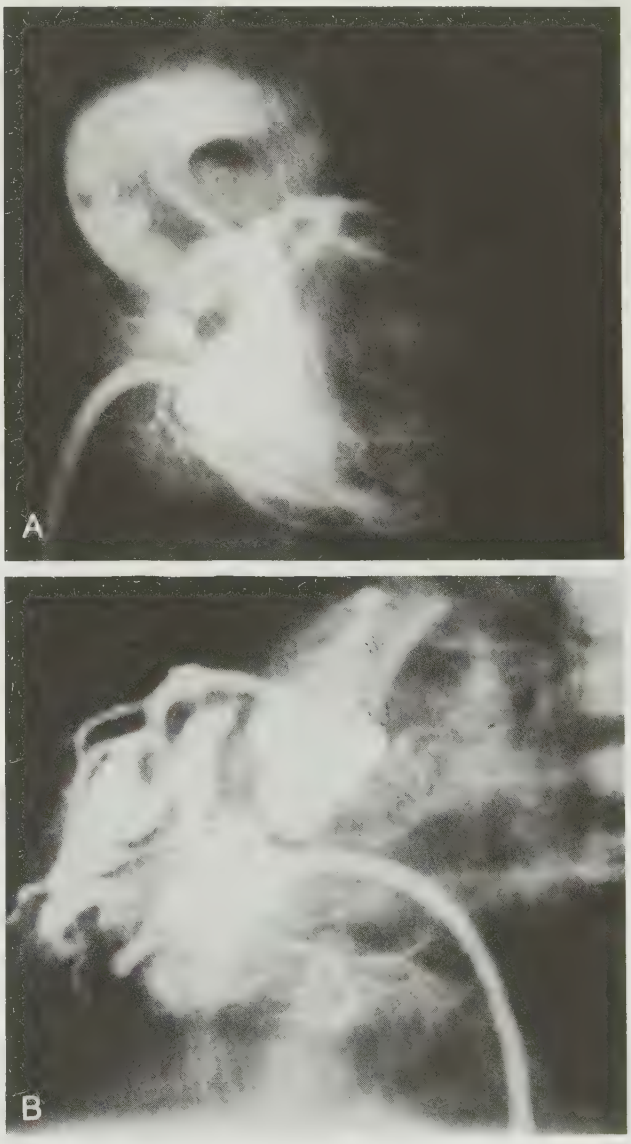

Fig. 65–5. (a) Anteroposterior and (b) lateral views of a right ventricular angiogram in a neonate with PA-IVS showing a very hypoplastic right ventricle and large right ventricular sinusoids communicating with the aorta via the coronary artery circulation.

Fig. 65–6. Right ventricular angiogram in a neonate with PA-IVS revealing a hypoplastic tripartite right ventricle, severe tricuspid insufficiency, and a large right atrium.

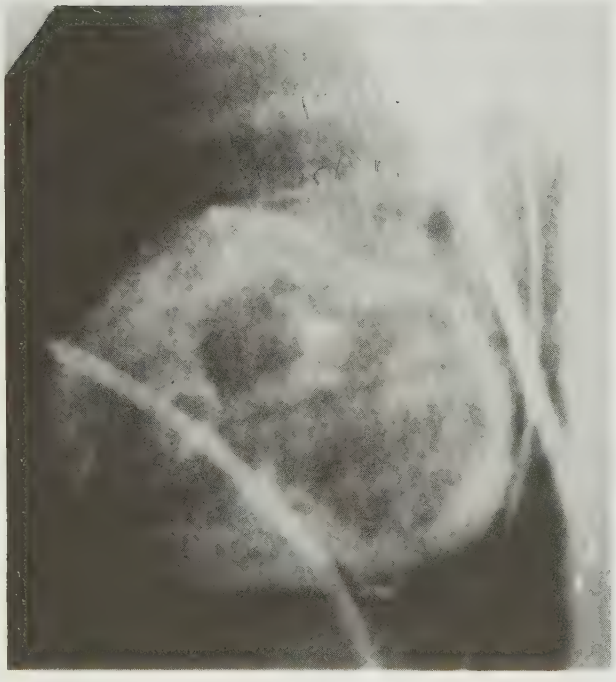

Fig. 65–7. Lateral view of a right ventricular angiogram in a patient with PA-IVS after the contrast material has almost cleared. The very small tricuspid orifice is well outlined, and accurate measurement is possible by comparing it to the 5F catheter.

main pulmonary artery. This distance can be adequately appreciated by opacification of both the main pulmonary artery and the right ventricle simultaneously with injection of contrast material in the descending aorta at the level of the ductus and in the right ventricle at the same time using two catheters as described by Freedom and colleagues.[63] The umbilical artery indwelling catheter can be used for the aortogram. An alternative method of ascertaining the distance is by labeling the tip of the outflow tract on the cine screen and noting its proximity to the pulmonary artery later in the injection as the aorta and pulmonary arteries opacify.

A left ventricular injection will show the size and function of the left ventricle and will eliminate the possibility of a ventricular septal defect. Good opacification of the aorta occurs if the catheter is well placed in the left ventricle, and the pulmonary arteries will opacify via the ductus arteriosus or other collateral circulation. A posteroanterior projection with cephalic angulation shows the anatomy and size of the branch pulmonary arteries, while the lateral projection reveals the presence or absence of a main pulmonary artery and shows its size. If a left ventricular injection is not possible with the venous catheter, then an aortogram should definitely be done either with the umbilical catheter or by introducing a retrograde catheter into the femoral artery. Left ventricular compliance and function measured at the time of the original catheterization are felt to be important to the eventual outcome of these infants.[64]

DIFFERENTIAL DIAGNOSIS

Other lesions to be considered in newborns with severe cyanosis include d-transpositon of the great arteries, tetralogy of Fallot with or without pulmonary atresia, severe pulmonary stenosis with intact ventricular septum, tricuspid atresia, and total anomalous pulmonary venous return with obstruction of pulmonary veins. Rarer defects include complex defects associated with asplenia or polysplenia syndromes and pulmonary atresia with endocardial cushion defect or pulmonary atresia with double-outlet right ventricle.

ASSOCIATED DEFECTS

PA-IVS usually occurs as a single lesion. However, it has been reported in L-transposition of the great arteries and ventricular inversion,[65,66] with Uhl's anomaly,[67,68] and with aortic valve stenosis.[40,43]

TREATMENT

Medical

Adequate treatment of PA-IVS begins in the neonatal period with the onset of symptoms. As soon as the diagnosis of heart disease with decreased pulmonary blood flow is made, access to the vascular system should be established and an infusion of prostaglandins started to re-establish pulmonary blood flow. This infusion should result in a pink baby with good peripheral perfusion and a normal acid-base balance. An arterial line should be established, most easily done in the umbilical artery, since the infant will need frequent determinations of arterial blood gases especially during and following surgery. Abnormalities of glucose, calcium, or other electrolytes should be corrected.

During cardiac catheterization, a balloon atrial septostomy should be performed. In older infants with an inadequate atrial communication, a transseptal puncture followed by blade septostomy or surgical septectomy might be required.

Surgical

Analysis of the anatomy delineated by the catheterization dictates the mode of surgical intervention required. The surgical treatment of PA-IVS has always been somewhat disappointing because of the high mortality rate from this defect, even when it has seemingly been well palliated. Generally, the goals of surgery have been to establish adequate pulmonary blood flow by either a systemic-to-pulmonary shunt or ductus infiltration with formalin[69] (now rarely done), to create a communication between the right ventricle and pulmonary artery, or a combination of these procedures. The order and timing of these interventions have varied over the years.

To best appreciate the current views on the surgical treatment of PA-IVS, we present a historical review of publications concerning the surgical approach to the defect. Of initial importance is the concept of the creation of systemic-to-pulmonary artery shunt advanced by Blalock and Taussig[70] in 1945 followed by another approach proposed by Potts and associates the following year.[71] Their suggestions remain an integral part of the treatment of PA-IVS to this day.

Direct surgical relief of stenotic pulmonary valves was reported almost simultaneously by Sellors[72] and Brock[73] in 1948. In the early 1950s, surgical relief of valvular pulmonic stenosis with intact ventricular septum became more common[74–76] and was performed in younger patients.[77] Until 1954, valvotomies were approached blindly through a transventricular puncture. In 1954, Swan and associates[78] described a transarterial approach in which the pulmonary valve was directly visualized and surgically opened. This technique was better suited for infants younger than 1 year.[79] In 1962, Benton and colleagues[80] reported attempts at pulmonary valvotomy in patients with PA-IVS with no survivors; and in 1967, Gerson and colleagues[49] reported dismal results of attempts at various types of operations on infants with PA-IVS.

Published series of the next decade were generally more encouraging.[46,48,57,60,81–90] It became evident that pulmonary valvotomy alone in infants with PA-IVS and tiny right ventricles did not suffice, and mortality remained high.[46,81] Systemic-to-pulmonary shunts combined with surgical atrial septectomies or balloon septostomies resulted in improved survival.[46,48,85,85] Greater success was achieved by staging surgery.[85] This was achieved by atrial septostomy at the time of catheterization followed by a systemic-to-pulmonary shunt and then pulmonary valvotomy several weeks or months later. In 1976, Trusler and associates[57] reported good success by balloon septostomy at catheterization followed by combined Potts anastomosis and pulmonary valvotomy at the same time. A more complete repair could then be accomplished later. It seemed that if blood flow through the right ventricle could be established, growth of the ventricular cavity might occur over time.[57,60,87,89,90] The use of prostaglandins in the late 1970s allowed infants to be in an improved state for the procedures, and overall survival increased.

The 1980s brought further refinement to the surgical treatment of PA-IVS. Patel and associates[36] analyzed factors that influenced the growth of the right ventricle postoperatively in patients with PA-IVS and focused attention to the size of the tricuspid valve as one of the limiting factors for allowing growth of the ventricle. The ability to establish right ventricular–pulmonary artery continuity was also felt to be an important criterion. The tripartite classification of the right ventricle of Bull and associates[25] elaborated on the factors necessary for the proper selection and timing of procedures.[27,40]

The use of Fontan-type anastomoses in hearts with very small tricuspid valves was reported in 1982.[27] Since then, a number of reports have been published describing improved results of surgery in PA-IVS.[40,91–103] Prior to a decision regarding complete correction, the use of balloon closure of the atrial communication during catheterization might help the physician to decide whether the right ventricle will accommodate the entire systemic venous flow.[91,104] In 1982, Puga and Uretzky described a method to establish continuity between the hypoplastic right ventricle and pulmonary artery without the use of extracorporeal circulation.[105] The presence of ventriculocoronary communications, which is associated with severe hypoplasia of the right ventricle and tricuspid valve, might be detrimental if the pressure in the ventricle is relieved.[32] Therefore a systemic-to-pulmonary shunt in the neonate followed later by the Fontan procedure might prove more successful.

A recent summary[103] suggests that the tricuspid valve should approach 70% of normal size for a good result from complete correction and that patients with smaller valves should have a modified Fontan procedure. In this series, patients undergoing eventual Fontan surgery had tricuspid valves that were an average of 44.4% of normal when measured angiographically. This approach summarizes current treatment of the defect.

PROGNOSIS AND FUTURE DEVELOPMENTS

Although some patients with PA-IVS have lived into early adulthood without surgery,[106–108] the prognosis of this lesion remains guarded, even with surgery. In 1978, Freedom and Keith[5] reported the experiences in Toronto and Buffalo with one third of cases dying by the second week of life and 50% dead by one month. In 1983, Lewis and colleagues[101] from Los Angeles reported a 33% mortality in 27 children with PA-IVS presenting between 1976 and 1982 who had undergone various surgical procedures. Surgical reports continue to improve.[100,102,103] However, since patient selection differs in the reported series, actual mortality rates are not comparable. The eventual outcome appears to depend on the presence or absence of sinusoid-coronary communications and the size of the tricuspid valve.

The use of newer imaging techniques such as nuclear magnetic resonance and positron emission tomography together with three-dimensional computer techniques of echocardiography will improve the noninvasive anatomical classification and measurements in patients with PA-IVS.

The use of autogenous skeletal muscle to enlarge a hypoplastic ventricle is a new concept that has appeal, since it has the potential of growth and would overcome the problems of tissue rejection of transplanted tissue. Attempts[109–111] to use autogenous skeletal muscle, usually the electrically stimulated diaphragm, have been unsuccessful because of muscle fatigue. Recently, there has been renewed interest in the use of skeletal muscle, especially with the development of fatigue resistance.[112–115] Macoviak and associates[116]

have successfully used latissimus dorsi muscle isolated with its neurovascular bundle and electrically stimulated to replace part of a right ventricle in dogs. This same preparation was also used[116] as a neoventricle to provide pulmonary blood flow where the right ventricle has been bypassed, as in the Fontan procedure. Thus the future treatment of PA-IVS should continue to improve as techniques are developed to replace or augment the right ventricle.

CHAPTER 66

Tricuspid Atresia

David J Driscoll

Tricuspid atresia, the third most common form of cyanotic congenital heart disease, consists of complete agenesis of the tricuspid valve and absence of direct communication between the right atrium and right ventricle.[1,2] The prevalence of tricuspid atresia in clinical series of patients with congenital heart disease ranges from 0.3 to 3.7%.[2] The prevalence rate in autopsy series is 2.9%.[2] Tricuspid atresia occurs in approximately 1 in 15,000 live births.[2] There is no apparent sex predilection if all forms of tricuspid atresia are considered; however, that associated with transposed great arteries occurs more commonly in males.[2–4] Kreysig described tricuspid atresia in 1817, and Kühne described it in 1906.[5–7]

PATHOLOGY

Tricuspid atresia is divided into three types (Table 66–1) on the basis of the great artery relationship: I, normally related great arteries; II, D-transposed great arteries; and III, L-transposed great arteries. Approximately 70% of cases are type I, 23% are type II, and 7% are type III.

The three types are subclassified according to the presence (or absence) and size of the ventricular septal defect and the presence (or absence) of pulmonary atresia or stenosis.[8,9]

Weinberg[10] classified tricuspid atresia into five types on the basis of the relationship of the systemic venous atrium to the underdeveloped right ventricle: A) *muscular atresia* (the most common type), no evidence of tricuspid valve tissue and the floor of the systemic venous atrium is muscular; B) *membranous atresia,* a portion of the right atrial floor is formed by a translucent membrane; C) *valvar atresia*, the floor of the systemic venous atrium contains a tiny imperforate valvelike structure; D) *Ebstein's form,* valvular tissue in the floor of the systemic atrium is adherent to the right ventricular wall, forming an "atrialized portion" of the right ventricle; and E) rarely, *common atrioventricular canal,* a leaflet of the common atrioventricular valve completely seals the only entrance to the right ventricle. Some investigators would exclude Weinberg's types D and E from tricuspid atresia, classifying these as Ebstein's anomaly with an imperforate valve and an unbalanced or left ventricular dominant atrioventricular canal defect, respectively.

Table 66–1. Classifications of Tricuspid Atresia

		Relative Frequency, %	
Type	*Description*	*Clinical*	*Autopsy*
I	Normally related great arteries	70	69
I-A	No VSD*; pulmonary atresia		9
I-B	Restrictive VSD; pulmonary stenosis		51
I-C	Large VSD; no pulmonary stenosis		9
II	D-Transposition of great arteries	23	28
II-A	VSD; pulmonary atresia		2
II-B	VSD; pulmonary stenosis		8
II-C	VSD; no pulmonary stenosis		18
III	L-Transposition of great arteries	7	3

Adapted from Rosenthal, A., and Dick, M.: Tricuspid atresia. *In* Moss' heart disease in infants, children, and adolescents. 3rd ed. Edited by F.H. Adams and G.C. Emmanouilides. Baltimore, Williams & Wilkins, 1983, pp. 271–283.

*VSD, ventricular septal defect

In tricuspid atresia the right ventricle is hypoplastic and may be a slitlike space concealed in the right wall of the left ventricle, a moderate-sized chamber with or without rudimentary papillary muscles, or a small chamber comprising a smooth-walled conus portion and a trabecular portion; however there is no sinus portion of the right ventricle (Fig. 66–1).[11]

Four types of ventricular septal defects can be associated with tricuspid atresia: 1) perimembranous type, 2) malalignment type, 3) muscular type, and 4) atrioventricular canal type. The perimembranous ventricular septal defect is located inferior to the parietal band, and the septal and parietal bands are relatively preserved. The conal septal malalignment defect occurs in a position normally occupied by the parietal band between the anterosuperior and posteroinferior septal bands. Muscular ventricular septal defects may be single or multiple and are located in the inferior aspect of the ventricular septum. The atrioventricular canal type (located in the posterior aspect of the septum) is rare. The ventricular septal defect may be, or may become, restrictive, producing subpulmonary or subaortic stenosis, depending on whether the great arteries are normal or transposed.

The pulmonary stenosis associated with tricuspid atresia can be valvular, subvalvular and unrelated to the ventricular septal defect, or due to a restrictive ventricular septal defect in patients with normally related great arteries. Pulmonary stenosis is more frequently associated with tricuspid atresia and normally related great arteries than with transposed great arteries. Although Weinberg[12] indicated that pulmonary stenosis is valvular in two-thirds of the patients with tricuspid atresia, other investigators believe that obstruction at the level of the ventricular septal defect is more common.

An opening in the atrial septum is necessary to allow egress of blood from the right atrium. In 80% of cases, there is a patent foramen ovale or a secundum atrial septal defect. Rarely, an ostium primum type of atrial septal defect is present. The interatrial communication can be or can become restrictive.

Additional cardiovascular abnormalities occur in 18% of patients with tricuspid atresia and normally related great arteries and in 63% of patients with transposed great arteries.[1,12,13] Persistence of the left superior vena cava with drainage into the coronary sinus occurs in 12 to 15% of patients with tricuspid atresia,[14] compared to 0.5% in the general population[15] and 4% in patients with congenital heart disease.[16] In the presence of bilateral superior venae cavae, the right superior vena cava may be too small (i.e., carry insufficient systemic venous return) to allow a successful Glenn anastomosis between the right superior vena cava and the right pulmonary artery. If an innominate vein connects the right and left superior venae cavae, blood flow may preferentially flow from the right superior vena cava and the Glenn anastomosis to the persistent left superior vena cava, reducing the effectiveness of the Glenn procedure. Rarely, the persistent left superior vena cava communicates directly with the atrium, a situation that must be identified and managed appropriately if the Fontan operation is contemplated.

Juxtaposed atrial appendages occur in 10% of all cases of tricuspid atresia but may be found in as many as 40% of cases of tricuspid atresia associated with transposed great arteries.[3,17] The presence of juxtaposed atrial appendages may necessitate alteration in the operative technique in establishing a right atrium-to-pulmonary artery connection for a modified Fontan operation.

Additional cardiovascular abnormalities associated with tricuspid atresia include coarctation of the aorta (8%), patent ductus arteriosus (3%), and right aortic arch (3 to 8%).[1,10,13] Extracardiac anomalies occur in 20% of the cases.[17]

After penetrating the central fibrous body of the heart, the bundle of His is related to the left ventricular aspect of the septum. However, the left bundle branch originates early from the bundle of His and is unusually more posteriorly located and shorter in tricuspid atresia than in the normal heart.[1,18] Presumably, this anatomic malformation of the conduction system accounts for the abnormal frontal plane axis of the electrocardiogram in patients with tricuspid atresia. The atrioventricular node is located in the

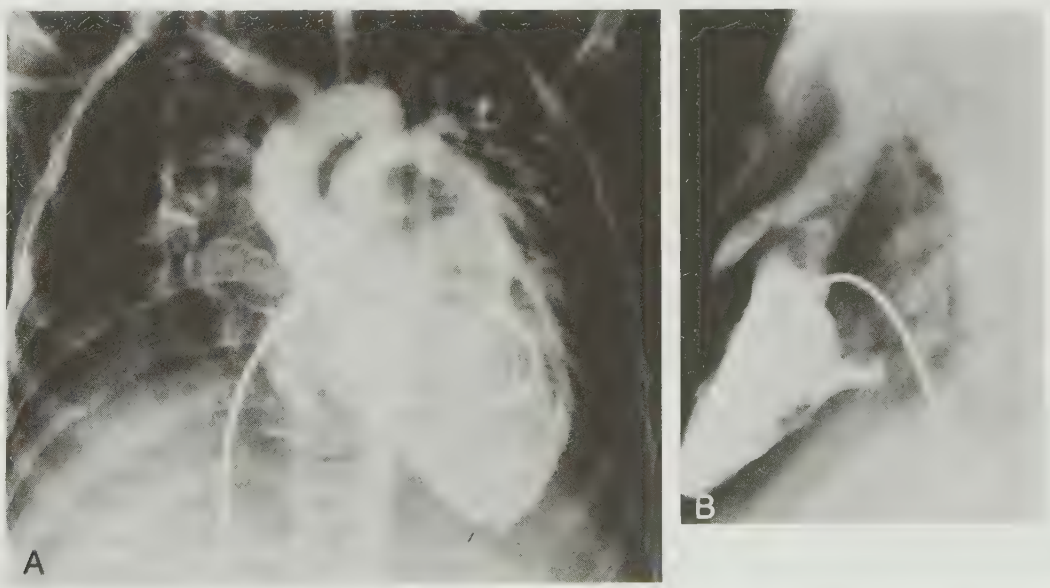

Fig. 66–1. A left ventriculogram in the anteroposterior and lateral projections in a patient with tricuspid atresia demonstrating a small right ventricle with absence of the inlet portion of the right ventricle. A restrictive ventriculoseptal defect is seen in the lateral projection.

region of the tendon of Todaro, and, unlike the abnormally located anterior atrioventricular node in some cases of univentricular heart, it is normally located posteriorly.

HEMODYNAMICS

Systemic venous blood returning to the right atrium can exit from the right atrium only through an interatrial communication (Fig. 66–2). If the interatrial communication is small, the right atrial pressure may be increased. However, with low cardiac output and a restrictive septal defect, a pressure difference between right and left atrium may be unimpressive. Because of the obligatory right-to-left shunt at atrial level, left atrial blood oxygen saturation is decreased but pulmonary venous blood saturation is normal.

In tricuspid atresia, the hemodynamics depend on the presence or absence of pulmonary atresia, the degree of pulmonary stenosis, the presence of normally related or transposed great arteries, and the presence or absence of subpulmonary or subaortic stenosis at the level of the ventricular septal defect. Because all systemic venous return (blood oxygen saturation low) and pulmonary venous return (blood oxygen saturation high) mix in the left atrium, the level of blood oxygen saturation reaching the left ventricle, and subsequently the aorta, depends on the relative volumes of pulmonary venous return and systemic venous return. Patients with tricuspid atresia and increased pulmonary blood flow (i.e., no pulmonary or subpulmonary stenosis) have a relatively larger volume of pulmonary venous return than systemic venous return and have relatively high systemic arterial blood oxygen saturation. In contrast, patients with relatively low pulmonary blood flow (due to pulmonary or subpulmonary stenosis or pulmonary atresia) may have marked systemic arterial hypoxemia. The volume of pulmonary blood flow and the clinical characteristics may change with time. Patients with pulmonary stenosis may be dependent on patency of the ductus arteriosus for pulmonary blood flow and, as the ductus closes, pulmonary blood flow may decrease significantly.

Fig. 66–2. A schematic diagram representing the course of blood flow in a heart with tricuspid atresia.

In general, pulmonary or subpulmonary (at the level of the ventricular septal defect) obstruction is present or occurs during the first year of life in most patients with tricuspid atresia and normally related great arteries. In contrast, most patients with tricuspid atresia and D-transposed great arteries (type II) have unobstructed pulmonary blood flow. Hence, patients in the former groups usually will have more marked hypoxemia than those with D-transposed great arteries, but those with D-transposed great arteries are more likely to have pulmonary edema and congestive heart failure and to develop pulmonary vascular obstructive disease. The ventricular septal defect associated with tricuspid atresia tends to become smaller with time. A restrictive ventricular septal defect associated with normally related great arteries produces progressive subpulmonary stenosis and increasing hypoxemia. A restrictive ventricular septal defect associated with transposed great arteries produces subaortic obstruction. When combined with pulmonary stenosis or the presence of a pulmonary artery band, significant left ventricular hypertension and hypertrophy occur. Severe left ventricular hypertrophy may affect the outcome of a Fontan operation adversely.

The major portion of the ventricular mass in tricuspid atresia is composed of left ventricle and functionally is a single ventricle. Because it receives all systemic and pulmonary venous return, the ventricle functions with a volume overload. This, in addition to long-standing hypoxemia, may contribute to ventricular fibrosis and decreased function that is manifested by increased left ventricular end-diastolic pressure and decreased ejection fraction. Decreased ventricular function may also result in mitral annular dilation and mitral insufficiency.

CLINICAL HISTORY

Because of the presence of cyanosis, congestive heart failure, or growth failure, tricuspid atresia usually is detected in infancy. At the Boston Children's Hospital, all but one patient with tricuspid atresia required hospitalization by 6 months of age.[1] In more than half of the patients, other symptoms of congenital heart disease developed in the first week of life, and 75% had cyanosis.[19]

The clinical presentation depends to a great degree on the amount of pulmonary blood flow. Cyanosis is the most prominent feature in patients whose pulmonary blood flow is limited by pulmonary atresia or pulmonary stenosis. Symptoms of pulmonary edema and congestive heart failure predominate in patients with unobstructed pulmonary blood flow; cyanosis also can be apparent. If pulmonary blood flow depends on the patency of the ductus arteriosus, the degree of cyanosis and arterial hypoxemia may increase dramatically if the ductus arteriosus closes. Indeed, if pulmonary atresia is present, closure of the ductus can produce

profound hypoxemia, acidosis, and death. Hypoxic spells have been reported in 16 to 45% of infants less than 6 months of age with tricuspid atresia, and death occurred in 4%.[1] Also, as pulmonary vascular resistance decreases and pulmonary blood flow increases in early infancy, the signs and symptoms of congestive heart failure and pulmonary edema can increase in patients who do not have pulmonary stenosis. Usually, however, the course in patients with normally related great arteries is one of aggressive cyanosis.

Growth failure is common in infants with tricuspid atresia. Dick[19] reported that 19% of such newborns were less than the fifth percentile for weight, suggesting intrauterine growth failure. Postnatal growth also was impaired: 58% of their patients were less than the fifth percentile for weight and 52% were less than the fifth percentile for height at the time of their last examination. Without surgical intervention, significant pulmonary vascular obstructive disease will occur in patients with unrestricted pulmonary blood flow (types I-C and II-C). Pulmonary vascular obstructive disease is much less common in patients with tricuspid atresia and normally related great arteries than in patients with transposed great arteries because the majority of patients with normally related great arteries have or develop either pulmonary or subpulmonary stenosis.

Bacterial endocarditis and brain abscess are relatively common complications of tricuspid atresia. Bacterial endocarditis occurs in 17 to 25% of patients with tricuspid atresia who have had a surgical systemic-to-pulmonary artery anastomosis. This represents one episode of endocarditis per 72 patient·years.[3,4] Brain abscess occurs in 1.3 to 5% of patients, representing one episode of brain abscess per 273 patient·years.[19,20] Brain abscess should be suspected in any patient with cyanotic congenital heart disease and headache, focal neurologic signs, or seizures. Neurologic complications also can result from cerebrovascular accidents secondary to polycythemia or to intravascular thrombosis or embolic phenomena.

Thoracolumbar scoliosis is common in patients with cyanotic congenital heart disease, and appropriate management is necessary to avoid significant pulmonary compromise as well as cosmetic disability.

PHYSICAL EXAMINATION

Inspection

Cyanosis is the most common clinical feature of tricuspid atresia, and the degree of cyanosis is dependent on the amount of pulmonary blood flow. In newborns with tricuspid atresia, pulmonary atresia, or stenosis, the amount of pulmonary blood flow is decreased, and cyanosis will worsen as the ductus arteriosus closes. Infants with tricuspid atresia and normally related great arteries may have excessive pulmonary blood flow and little cyanosis. As the ventricular septal defect becomes progressively more restrictive, causing subpulmonary stenosis and decreasing blood flow, signs and symptoms of congestive failure and pulmonary edema will lessen and the degree of cyanosis will increase. Because of cyanosis and polycythemia, digital clubbing is common after 3 months of age. Jugular venous pulsations are difficult to assess in infants. In children and adults with tricuspid atresia the jugular venous pulsations can be abnormal. A prominent a wave can occur if the interatrial communication is restrictive, and a prominent v wave may be found in the presence of mitral insufficiency with an unrestricted interatrial communication.

Palpation

The peripheral pulses and pulse volume may be normal, increased, or decreased. Patients with a patent ductus arteriosus, numerous or large aorticopulmonary collateral vessels, or a surgically created systemic-to-pulmonary artery anastomosis may have an increased pulse volume. A discrepancy between the upper and lower extremity pulse volumes is indicative of associated coarctation of the aorta. The pulse volume may be decreased in patients with transposed great arteries and a restrictive ventricular septal defect (subaortic stenosis). The peripheral arterial pulses should be normal in patients without a surgically created aorticopulmonary anastomosis with a closed ductus arteriosus, absence of aorticopulmonary collateral vessels, and no coarctation of the aorta. The peripheral pulses are unaffected by a Glenn anastomosis.

Tricuspid atresia is one form of cyanotic congenital heart disease that results in the left ventricular impulse being more prominent than the right ventricular impulse. Because the left ventricle is subjected to volume overload, the apical impulse is overactive and usually is displaced to or beyond the left midclavicular line. Closure of the aortic valve may be palpable at the upper left sternal border in patients with tricuspid atresia and transposed great arteries. A thrill may be felt at the left sternal border in patients with pulmonary stenosis or restrictive ventricular septal defect. The liver may be enlarged and pulsatile, especially if there is a restrictive interatrial communication or mitral insufficiency.

Auscultation

The first heart sound is single but may be of increased intensity. The second heart sound may be single or split normally with respiration. The intensity of the second heart sound usually is normal if the great arteries are normally related and the pulmonary artery pressure is normal. Because of the proximity of the aorta to the anterior chest wall when transposed great arteries are present (i.e., the aorta is anterior to the pulmonary artery), the second heart sound may be increased in intensity despite normal pulmonary artery pressure.

Cardiac murmurs are present in 80% of patients with tricuspid atresia.[13] A low-frequency holosystolic or, at times, crescendo-decrescendo murmur will be produced from blood flowing through the ventricular septal defect. A systolic midfrequency crescendo-decrescendo murmur is present in patients with pulmonary stenosis. Patients with pulmonary atresia and a systemic-to-pulmonary collateral blood supply, as well as patients who have had a surgical systemic arterial-to-pulmonary arterial anastomosis, have a continuous murmur. In contrast, murmurs are not produced by an unobstructed Glenn anastomosis (connection of superior vena cava to right pulmonary artery). A diastolic mitral murmur may be audible in patients who have excessive pulmonary blood flow. A murmur of mitral insufficiency may occur, but frequently other systolic murmurs obscure this murmur even if mitral insufficiency is present.

ELECTROCARDIOGRAM

The cardiac rhythm in tricuspid atresia usually is sinus with tall P waves suggesting atrial enlargement (Fig. 66–3). First-degree

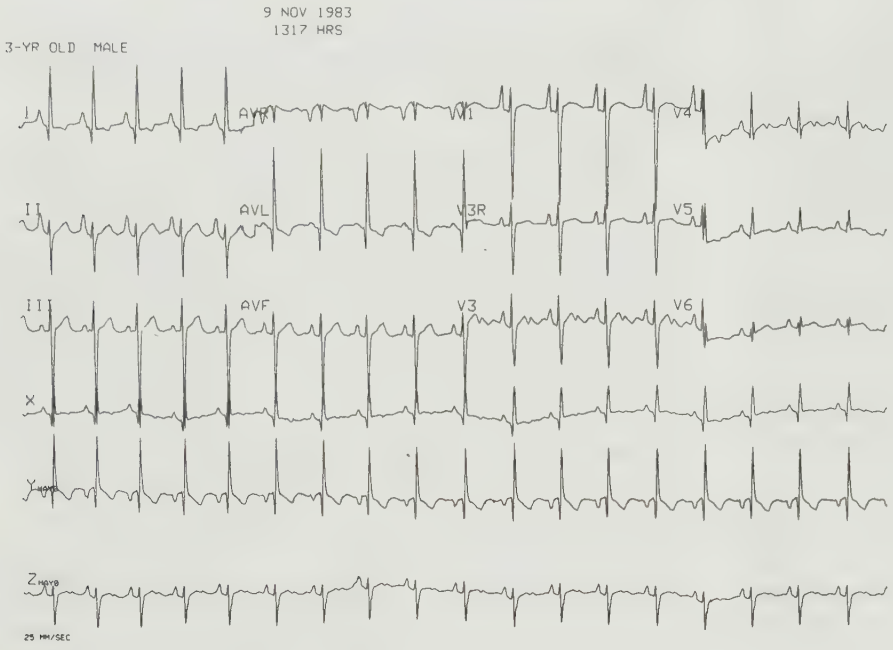

Fig. 66–3. An electrocardiogram from a patient with tricuspid atresia. The frontal plane QRS axis shows left axis deviation. The P waves are tall and peaked, suggesting right atrial enlargement. Anterior (right ventricular) forces are relatively diminished.

atrioventricular block occurs (15% of cases). This presumably is due to prolonged intra-arterial conduction because atrioventricular node function usually is normal.[1] Because of early origin of the left bundle branch from the common bundle, the frontal plane QRS axis usually is leftward or superior. Rarely, the frontal plane QRS axis is normal, which suggests the presence of transposed great arteries.[13,21] Right ventricular electrocardiographic forces are diminished and there is evidence of left ventricular hypertrophy. Frequently discordant QRS and T waves are seen. There is poor correlation between P-wave amplitude and interatrial communication size. There is poor correlation between the amplitude of the QRS and the ventricular septal defect size or ventricular wall thickness.[21]

The surface electrocardiographic tracing may suggest the presence of preexcitation (i.e., short PR interval and apparent delta wave) in 9% of patients with tricuspid atresia, but an atrioventricular bypass tract can be demonstrated less frequently (T. Zellers, personal communication).

CHEST RADIOGRAPH

The heart usually is enlarged. Heart size depends upon the amount of pulmonary blood flow and the presence or absence of mitral insufficiency. The right heart border frequently is prominent reflecting enlargement of the right atrium. The pulmonary vascular markings are increased when the pulmonary blood flow is excessive. In 80% of patients with tricuspid atresia, the pulmonary blood flow is diminished and the pulmonary vascular markings are decreased.[22] A right aortic arch occurs in 3 to 8% of cases.[1,13]

ECHOCARDIOGRAM

Echocardiography can provide the diagnosis of tricuspid atresia and delineation of anatomic details and associated abnormalities.[23] The basic anatomy, the size of the atrial septal defect, the size of the ventricular septal defect, ventricular function, great artery relationships, and valvular function can be ascertained by using M-mode, two-dimensional, and color-flow imaging echocardiography. Relatively accurate estimates of pressure gradients (pulmonary stenosis, subaortic stenosis) can be made with Doppler techniques. Associated abnormalities, such as coarctation of the aorta, persistent left superior vena cava, and juxtaposed atrial appendages,[24] can be detected.

CARDIAC CATHETERIZATION

The role of cardiac catheterization in determining anatomic and hemodynamic details in congenital heart disease has changed dramatically with the increasing sophistication of noninvasive imaging techniques (echocardiography, magnetic resonance imaging). If one has high-quality noninvasive diagnostic imaging techniques available, cardiac catheterization no longer is required to determine the presence of tricuspid atresia, great artery relationships, presence or absence of pulmonary stenosis, or the size of the interatrial communication. The role of cardiac catheterization depends to a large extent upon the patient's age.

In infants, the major use of cardiac catheterization is for determining the sources and reliability of pulmonary blood flow. With associated pulmonary atresia or severe pulmonary stenosis, patent ductus arteriosus may be the only source of sufficient pulmonary blood flow. Ventriculography or aortography, or both, may be necessary to document an alternate source of pulmonary blood flow, such as systemic-to-pulmonary artery collateral vessels. The administration of prostaglandin E_1 to maintain ductal patency has improved the safety of cardiac catheterization for babies with decreased pulmonary blood flow. Cardiac catheterization may be necessary in infants (2 to 6 months of age) for measurement of pulmonary artery pressure and resistance, as a guide to the need of pulmonary artery banding to prevent the development of pulmonary vascular obstructive disease. Some investigators recommend balloon atrial septostomy for all infants with tricuspid atresia. Others indicate that only a small subset of infants with tricuspid atresia have a restrictive interatrial communication, and septostomy should be done only in this subset of patients. If a systemic-to-pulmonary shunt is performed, it is

thought by some that the increased volume of blood returning to the left atrium may tend to close the valve of the foramen ovale. For this reason, some investigators perform balloon septostomy immediately before or after aorticopulmonary shunt. Occasionally, a previously unrestrictive interatrial communication becomes restrictive. In these cases the Park blade atrial septostomy technique can be used to enlarge the interatrial communication.[25]

In adolescents and adults, cardiac catheterization and angiography are used to define anatomic and hemodynamic details important in surgical management. If a Glenn anastomosis is contemplated, the presence of bilateral superior venae cavae must be excluded and the size and location of the single superior vena cava must be established. The presence of bilateral superior venae cavae will affect the function of the Glenn anastomosis adversely.

It is necessary to perform cardiac catheterization and angiography to obtain much of the following information that is important to have when a modified Fontan operation is being considered: 1) pulmonary artery size, distribution, and presence of pulmonary artery distortion from previous aorticopulmonary shunt, 2) pulmonary arteriolar resistance, 3) left ventricular function and end-diastolic pressure, 4) presence and severity of subaortic obstruction (especially in patients with transposed great arteries), 5) mitral valve competency, 6) presence and location of anomalous systemic or pulmonary venous drainage, and 7) presence of pulmonary arteriovenous fistula resulting from prior Glenn anastomosis.

CLINICAL MANAGEMENT

Infants

Three major considerations should guide the management of infants with tricuspid atresia: 1) manipulation of the amount of pulmonary blood flow, either to decrease hypoxemia and polycythemia by increasing pulmonary blood flow or to decrease symptoms of congestive heart failure by decreasing pulmonary blood flow, 2) preservation of myocardial function, pulmonary vascular integrity, and the pulmonary vascular bed to optimize conditions for future Fontan operation, and 3) reduction of risks of associated cardiovascular complications such as bacterial endocarditis and thromboembolism.

Most infants with tricuspid atresia have decreased pulmonary blood flow, marked cyanosis, and hypoxemia. With significant hypoxemia (systemic arterial oxygen tension less than 25 to 30 mm Hg), acidemia may occur and death ensue. These babies with severe hypoxemia should be treated promptly with an infusion of prostaglandin E_1 to maintain patency of the ductus arteriosus and thus improve pulmonary perfusion. Cardiac catheterization and angiography will be necessary to establish the sources of pulmonary blood flow and to plan for the appropriate type of surgical systemic-to-pulmonary artery anastomosis. A modified Blalock-Taussig shunt is the preferred systemic-to-pulmonary artery anastomosis for increasing pulmonary blood flow in infants with unacceptable levels of hypoxemia. This type of shunt is associated with the least amount of pulmonary artery distortion and the greatest degree of control of the amount of pulmonary blood flow. The Waterston-Cooley shunt often results in distortion of the right pulmonary artery and unequal perfusion to the two lungs (Fig. 66–4). A Potts shunt should be avoided. The Potts shunt has disadvantages similar to the those of the Waterston-Cooley anastomosis, and, in addition, is still very difficult to remove at the time of Fontan operation.

Unfortunately, it is not feasible to perform a Glenn anastomosis in infants. However, in older children with tricuspid atresia, a Glenn anastomosis is attractive because, unlike systemic-to-pulmonary artery shunts, it does not produce an increased volume of blood for the ventricle to manage. A disadvantage of the Glenn anastomosis is the associated development of arteriovenous fistulae in the lung.

Infants with transposed great arteries and unrestricted pulmonary blood flow have signs and symptoms of pulmonary edema and congestive heart failure. They benefit from treatment with digitalis and diuretics. In most infants with tricuspid atresia and normally related great arteries who have unrestricted pulmonary blood flow in the newborn period, progressive subpulmonary obstruction develops and by age 1 year they have had sufficient reduction of pulmonary blood flow to ameliorate the symptoms of congestive heart failure and pulmonary edema. Indeed, rarely does a patient with tricuspid atresia and normally related great arteries require pulmonary banding to relieve symptoms related to increased pulmonary blood flow. However, these patients may require pulmonary artery banding to preserve normal pulmonary arteriolar resistance if an eventual Fontan operation is contemplated.

Infants with tricuspid atresia and transposed great arteries frequently have unrestricted pulmonary blood flow and signs and symptoms of pulmonary edema and congestive heart failure. They will require a surgical procedure to decrease pulmonary blood flow. Unfortunately, pulmonary artery banding in these patients may be associated with accelerated narrowing of the ventricular septal defect and, because of the presence of transposed great arteries, significant subaortic obstruction.[26] A combination of subaortic obstruction and pulmonary artery obstruction by the pulmonary band results in marked ventricular hypertrophy and significantly increases the risk of mortality or complications at the time of eventual physiologic correction using the Fontan operation.[27] Patients who have tricuspid atresia and transposition of the great arteries and who have had a pulmonary artery band require careful ongoing surveillance to detect development of subaortic obstruction. That obstruction must be relieved when it becomes significant.

Intelligent application of palliative procedures to control the amount of pulmonary blood flow significantly improves survival of infants with tricuspid atresia. With standard palliative surgical treatment, 50% or more of these patients survive to age 15 years.[3] However, these patients still are at risk for complications resulting from intracardiac right-to-left shunt such as paradoxic emboli, brain abscess, polycythemia, and stroke. They also remain at risk for developing the complications of chronic ventricular volume overload such as progressive cardiac dilation, myocardial fibrosis, ventricular dysfunction, mitral valve regurgitation, and arrhythmias.

Children and Adolescents

Until Fontan and Baudet[28] developed the concept of ventricular exclusion, palliative procedures to control pulmonary blood flow were the mainstay of surgical therapy for patients with tricuspid atresia. Fontan and Baudet constructed a Glenn anastomosis to direct superior vena caval systemic venous return to the right lung,

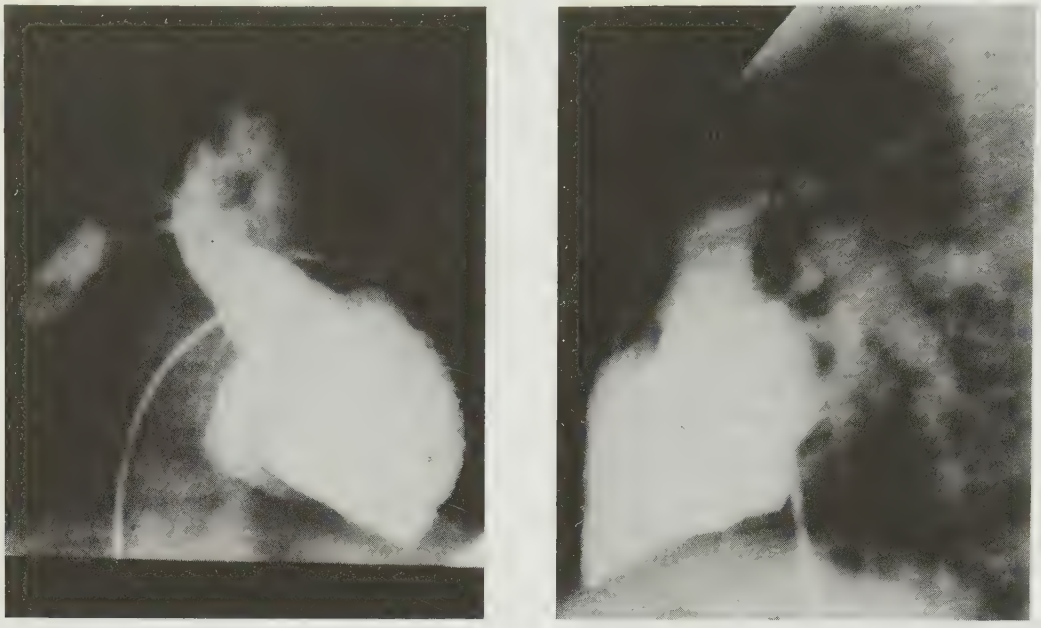

Fig. 66–4. Cineangiograms demonstrating distortion of the right pulmonary artery in association with a Waterston-Cooley shunt.

directed inferior vena caval systemic venous return to the pulmonary artery with a valve-containing conduit connecting the right atrium and pulmonary artery, inserted a valve into the inferior vena cava, closed the interatrial communication, and obliterated the connection between the pulmonary artery and the ventricle. Since the original description, the procedure has been modified considerably (Fig. 66–5), but the concept of directing systemic venous return directly to the pulmonary artery retains the eponym "modified Fontan procedure." It has become clear that use of prosthetic valves in the inferior vena cava and the right atrium-to-pulmonary artery connection is unnecessary. Prosthetic valves may be detrimental because of their tendency to malfunction and cause obstruction. Also, both superior vena caval and inferior vena caval systemic venous return can be directed from the right atrium to the pulmonary artery without utilizing a Glenn anastomosis. If there is a right ventricular remnant of reasonable size and a normal pulmonary valve, directing systemic venous return to the hypoplastic right ventricle with closure of the ventricular septal defect is advocated by some investigators rather than directing blood flow from right atrium to the pulmonary artery. Lee et al.[29] reviewed a series of patients with this type of connection and found no difference in operative survival or longterm results compared with those patients who had a right atrial-to-pulmonary artery connection.

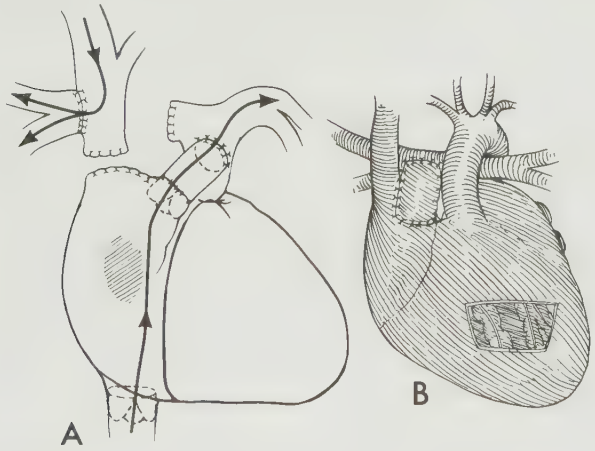

Fig. 66–5. (A) A diagram of the original procedure described by Fontan with prosthetic valves in the inferior vena cava and the connection between the right atrium and the main pulmonary artery. The superior vena cava is anastomosed to the right pulmonary artery. (B) The modified Fontan procedure, without prosthetic valves, and connection of the right atrium to a confluent pulmonary artery system.

Choussat and associates[30] developed ten guidelines for relatively low-risk operation (Table 66–2). It must be recognized that these are guidelines. Absence of one or more of these criteria does not eliminate the possibility of a modified Fontan operation. For example, Humes and associates[31] reported an operative mortality of 8% in 59 patients over age 17, a mortality not different from that of other age groups in his series. Also, in properly selected cases, the operation can be done at ages less than 4 years. Alboliras and

Table 66–2. Criteria of Choussat and Fontan for Low-Risk Operation

1.	Age at operation, 4 to 15 years
2.	Sinus rhythm
3.	Normal systemic venous return
4.	Normal right atrial volume
5.	Mean pulmonary artery pressure $\leq$15 mm Hg
6.	Pulmonary arteriolar resistance $<$4 units·m^2
7.	Pulmonary artery/aorta diameter ratio $>$0.75
8.	Left ventricular ejection fraction $\geq$0.60
9.	Competent mitral valve
10.	Absence of pulmonary artery distortion

Adapted from Choussat, A., et al.: Selection criteria for Fontan's procedure. *In* Pediatric Cardiology 1977. Edited by R.H. Anderson and E.A. Shinebourne. Edinburgh, Churchill Livingstone, 1978, pp. 559–566.

associates[32] reported an operative mortality of 25% for 12 patients who were not in sinus rhythm prior to operation. In addition, all 12 of these patients failed to fulfill 2 to 7 of the remaining 9 criteria of Choussat and associates.

Abnormal systemic and pulmonary venous connections can pose a challenge to the surgeon. With innovative intra-atrial baffle and conduit techniques to redirect blood flow to the pulmonary arteries, however, the Fontan operation can be performed successfully in spite of anomalies of venous connection. For example, a persistent left superior vena cava entering the dome of the left atrium can be anastomosed to the left pulmonary artery and the communication with the atrium obliterated. Systemic venous return of the right superior vena cava and inferior vena cava can be directed to the main pulmonary artery and right pulmonary artery, respectively in the usual fashion. The level of pulmonary arteriolar resistance is perhaps the most important criterion. It is unwise to recommend a modified Fontan operation if the pulmonary arteriolar resistance is above 4 units·m^2. On the other hand, increased pulmonary artery pressure is not a contraindication *if* the pulmonary resistance is less than 4 units·m^2. Mitral regurgitation can be managed with mitral valve annuloplasty or replacement. Kinking of pulmonary arteries from prior shunt procedures sometimes can be repaired to allow a successful modified Fontan operation. Patients with a longstanding Glenn anastomosis and acquired pulmonary arteriovenous fistulae present a unique problem as candidates for the Fontan operation. Because of the arteriovenous fistulae, they will remain hypoxemic (the degree of persistent hypoxemia depends upon the magnitude of the right-to-left shunt through the fistulae) after the Fontan operation. Attempts to eliminate the hypoxemia by repositioning the atrial septum to allow the right lower pulmonary vein to enter the right atrium (instead of the left) have been unsuccessful and should not be done. This technique is unsuccessful because the pulmonary artery pressure and the right lower pulmonary vein pressure become equal. Segmental pulmonary infarction occurs because of poor pulmonary blood flow.

Although the criteria of Choussat and Fontan are guidelines to low-risk Fontan operation and the operation can be done in the absence of some of these criteria, operative mortality and perhaps morbidity increase as more and more of these criteria are violated.

Postrepair right atrial pressure is a useful predictor of survival after the modified Fontan operation. In general, a postrepair mean right atrial pressure greater than 20 mm Hg portends a poor outcome. Kirklin, et al.[33] reported risk of death less than 12.5% if the mean right atrial pressure postrepair was less than 14 mm Hg but 43% if it was 19 mm Hg. Postrepair right atrial pressure reflects the adequacy of the right atrial-pulmonary artery anastomosis, pulmonary artery size, pulmonary arteriolar resistance, left atrial pressure, and left ventricular end-diastolic pressure. If one assumes a minimum 8 mm Hg transpulmonary pressure gradient postoperatively, a rough prediction of postoperative mean right atrial pressure can be made based upon preoperative assessment of left ventricular function, pulmonary artery size, and pulmonary arteriolar resistance.

Presumably the volume of the functional single ventricle should decrease after the modified Fontan operation and preliminary data suggest that this is so. Sanders, et al.[34] measured left ventricular ejection fraction before and after operation in 11 patients with tricuspid atresia who had a modified Fontan operation. Left ventricular ejection fraction remained normal postoperatively in 10 of these patients. In one case left ventricular ejection fraction was reduced preoperatively and remained reduced postoperatively.

Humes and associates[35] reviewed the results of the modified Fontan operation for patients with tricuspid atresia at the Mayo Clinic. Through June 1985, 134 patients with tricuspid atresia had a modified Fontan operation with an operative mortality of 10%. In addition, there were 11 late deaths. One-year survival was 85% and 5-year survival was 78%. Most of the survivors were doing well. Most of the patients reviewed by Humes failed to fulfill all of the criteria for low-risk operation. Operative mortality was less than 5% for patients fulfilling all, or all but one, of the criteria. Because the Fontan operation eliminates cyanosis and polycythemia and because the left ventricular volume overload is relieved, theoretically the operation should prolong life. Although there are early indications that it does prolong survival,[36] further longterm followup studies are necessary before this can be concluded firmly.

Most patients feel better after the Fontan operation, and exercise tolerance increases. Driscoll and associates[37] measured exercise tolerance in 33 patients with tricuspid atresia before Fontan operation and in 16 patients after operation. Maximal oxygen uptake increased from 39% of predicted preoperatively to 50% of predicted postoperatively. Systemic arterial blood oxygen saturation increased from 83 to 93% at rest and from 57 to 91% at peak exercise.

The modified Fontan operation can be performed with a low operative mortality, particularly in patients with tricuspid atresia who fulfill most of the Choussat and Fontan criteria for low-risk operation. Quality of life and exercise tolerance improve after operation. Preliminary data suggest that the operation prolongs life.[36] However, some patients continue to have problems postoperatively. These difficulties include fluid retention with ascites and peripheral edema, protein-losing enteropathy, and rarely, liver fibrosis.[38] Recurrence of an interatrial communication, dysfunction of a valve prosthesis, or spontaneous closure of a ventricular septal defect in patients with transposed great arteries may necessitate reoperation. Although some patients have persistent postoperative problems, in most circumstances the Fontan operation probably represents an improvement over the natural history of this malformation.

CHAPTER 67

Truncus Arteriosus

Robert L Williams
Robert J Sommerville

Persistent truncus arteriosus may be defined as a single great artery arising from the base of the heart giving origin to the coronary, pulmonary, and systemic arteries.[1,2] The earliest known descriptions of this defect were by Wilson in 1798,[3] and Buchanan in 1864.[4] The incidence of truncus arteriosus is rare, occurring in approximately 2% of patients with congenital heart defects.[5] There is no apparent gender predilection. Without treatment, truncus arteriosus is usually fatal, with the mean age of death at 2.5 months[6] and 80% of affected children dying by 1 year of age.[7]

EMBRYOLOGY

There are two embryologic theories on the development of truncus arteriosus. Classically, it is thought that the normal differentiation of the truncus into aorta and pulmonary artery is created by two ridges that appear in the conotruncal segment of the 4 to 5 mm (or 4 to 5 week) embryo. A spiral dextrodorsal ridge distally becomes continuous with a spiral sinistroventral ridge proximally. These two ridges grow toward the midline and become fused to form the conotruncal septum, which divides the truncus into the aorta and pulmonary artery with a 180° rotation.[8]

The semilunar valve site is marked by thickenings in the conotruncal ridge at the conotruncal junction. The right extension of the interventricular septum eventually coalesces with the conal portion of the conotruncal septum, thus separating the right and left ventricular outflow tracts.

The alternative theory was proposed by Van Praagh and Van Praagh. In their hypothesis, the 180° twisting of the great arteries about one another arises from the looping of the primitive ventricles to the right and subsequent differential conal growth forces the rotation of the aortic and pulmonary valves about a fixed point of the fourth and sixth arches. Van Praagh and Van Praagh have suggested that tetralogy and persistent truncus arteriosus may in fact be "first cousins"[6]; that is, persistent truncus arteriosus represents a form of tetralogy having pulmonary and infundibular atresia combined with failure of truncal separation.

ANATOMY

In 1949, Collett and Edwards proposed a classification based on embryologic theory and on their observations of 116 cases of persistent truncus arteriosus.[1] These authors classified (persistent) truncus arteriosus into 4 major types, based on the embryonic stage at which the development of the pulmonary arteries from the sixth aortic arches was arrested:

- Type 1—a single pulmonary trunk and ascending aorta arise from the truncus arteriosus.
- Type 2—the right and left pulmonary arteries arise close together from the dorsal wall of the truncus arteriosus.
- Type 3—one or both pulmonary arteries arise independently from either side of the truncus arteriosus.
- Type 4—no pulmonary arteries originate from the truncus and there is apparent absence of the sixth aortic arches. Pulmonary artery circulation is provided solely by bronchial arteries.

According to this classification, type 4 signifies arrested development at the earliest stage of the sixth aortic arches, since there is no development of the pulmonary arteries present. Types 3 and 2 represent arrested development at less primitive stages. Type 1

indicates arrested development at a much later stage with a portion of the common pulmonary trunk present (Fig. 67–1).

In 1965, Van Praagh proposed a new classification for truncus arteriosus. This classification is more complete and accurate than the classical one of Collett and Edwards (Fig. 67–1). Van Praagh classified two basic types—type A, with a VSD, and type B, without a VSD (rare). Both types are subdivided in terms of the great arteries: type 1—the aorticopulmonary septum is partially formed resulting in a partially separate main pulmonary artery; type 2—the aorticopulmonary septum is entirely absent, hence no discrete main pulmonary artery, with both pulmonary artery branches arising directly from the common trunk; type 3—absence of one pulmonary artery branch (either), this lung being supplied by collateral vessels; and type 4—the aortic isthmus displays hypoplasia, coarctation, atresia or absence, associated with a large patent ductus arteriosus. The vast majority of truncal cases have ventricular septal defect and belong to group A of Van Praagh. Group B recognizes the existence of persistent truncus without a ventricular septal defect.[9] Most authors, including Edwards,[10] agree that the type 4 Collett and Edwards classification does not represent a persistent truncus arteriosus, but rather an extreme form of tetralogy with main pulmonary artery atresia and commonly described today as pseudotruncus. In pseudotruncus the aortic pulmonary trunk is represented by a hard-to-find fibrous strand often identified only microscopically. Hemitruncus is not a true variant of truncus arteriosus, but a distinct anomaly in which conal-truncal division is complete. There is a pulmonary valve and a main pulmonary artery present, which gives rise to only one pulmonary artery branch. The pulmonary artery branch to the opposite lung arises directly from the ascending aorta.

Persistence of the truncus arteriosus almost always occurs in the presence of a ventricular septal defect. The truncal root straddles the ventricular septal defect equally in approximately 60% of cases with 20% each of the remaining cases having either a dominant right or left ventricular override.[11,12]

The truncal valve leaflets are usually abnormal and frequently appear thick, fleshy, soft, and polypoid. The number of leaflets varies. Approximately 65% have tricuspid valves; quadricuspid valves are present in 23% and bicuspid valves in approximately 9%. In 2% of cases, there may be five or more valve leaflets.[2,12] The truncal valve usually has fibrous continuity with the mitral valve and approximately 4 to 10% of cases may have a fibrous continuity with the tricuspid valve.[2,11] Truncal valve regurgitation is present in approximately 50% of patients, with half of these being moderate to severe.[13] Truncal valve stenosis may be seen in about one-third of patients, with a gradient ranging from 10 mm Hg to 60 mm Hg.[5]

Associated Abnormalities

The aortic arch is right-sided in about one-third of cases.[5] Persistent left superior vena cava is found in approximately 12% of cases. Partial anomalous pulmonary venous return is unusual, occurring approximately 1% of the time.[2,6] Abnormal origin of the coronary arteries is frequent.[12,14] A single coronary artery occurs

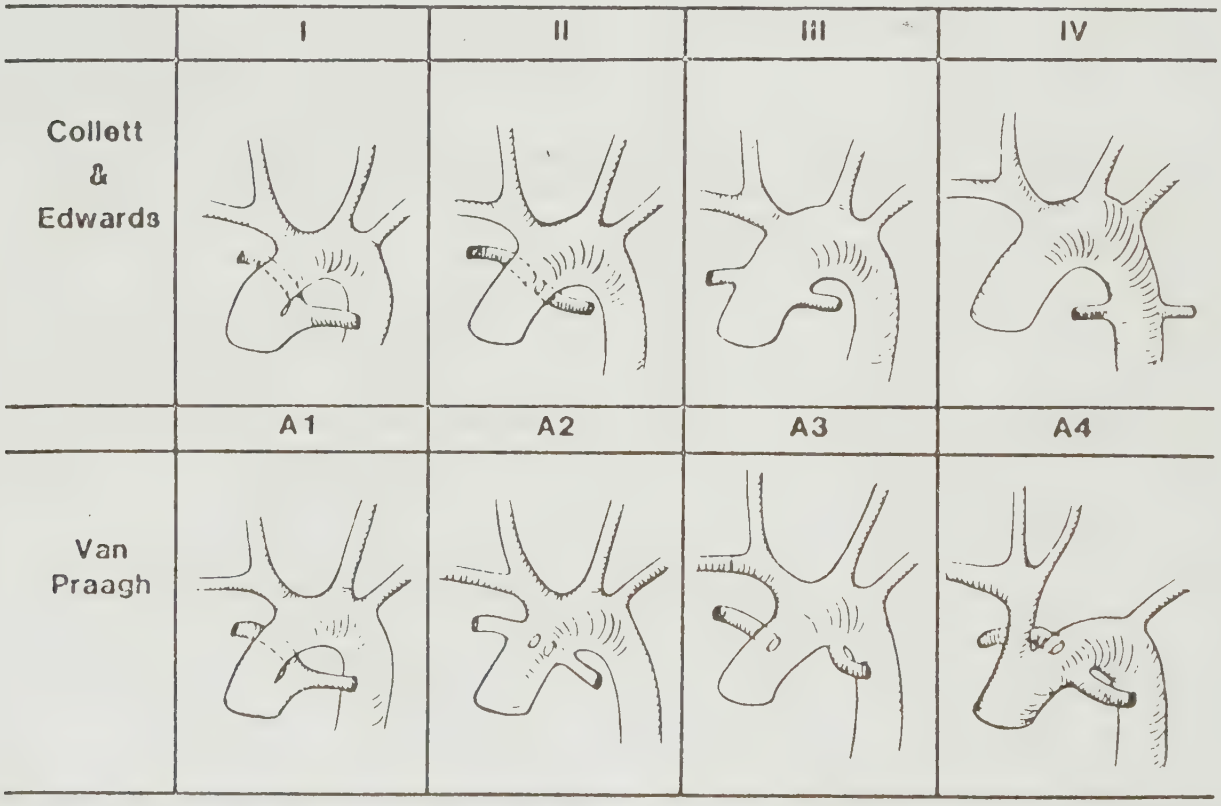

Fig. 67–1. Types of truncus arteriosus. The top row is modified from Collett and Edwards[1] and is still commonly referred to today. The bottom row is from Van Praagh and Van Praagh.[6]

in 13% of cases with truncus arteriosus. The coronary arteries may be separate, but near each other, arising from the same coronary sinus (10%). The left coronary artery tends to arise from a more posterior level than it does normally from the aorta. Anomalies of the posterior descending coronary artery branches are also common. The anatomy of the coronary arteries is of significance at the time of the surgical repair.

Tricuspid atresia and complete endocardial cushion defects have been reported with truncus arteriosus, as well as single ventricle.[15,16] Only one case of truncus arteriosus with intact ventricular septum has been reported.[9]

In approximately 12% of interrupted aortic anomalies, there is an associated truncus arteriosus.[17,18] Crisscross pulmonary arteries (a rare condition where the left pulmonary artery originates to the right of the origin of the right pulmonary artery, thus causing the pulmonary arteries to crisscross as they course to the respective lungs) is most frequently associated with truncus arteriosus and interrupted aortic arch.

Noncardiac anomalies are present in approximately 20% of cases.[6] DiGeorge's syndrome is one of the more common associated anomalies. Conversely, in those patients having DiGeorge's syndrome, which may be an autosomal dominant inheritance, approximately 26% have truncus arteriosus.[19,20] In those with DiGeorge's syndrome with interrupted arch, 33% have truncus arteriosus.[21]

PATHOPHYSIOLOGY

In truncus arteriosus there is obligatory mixing of the systemic venous and pulmonary venous blood at the level of the VSD and the base of the truncus. However, due to preferential streaming flow patterns the pulmonary artery saturation is often 10% lower than the systemic arterial saturation and truncus is not a total mixing lesion. The resultant systemic arterial saturation depends on the total volume of pulmonary blood flow, which varies inversely with the pulmonary arteriolar resistance. In the young infant, the pulmonary blood flow is often high because of the systemic pressure perfusing the pulmonary arteries with a relatively low resistance. This increased pulmonary vascular volume overloads the left heart and therefore symptoms of congestive heart failure are common at a very young age. At this stage of high pulmonary blood flow, there is minimal or no cyanosis. Progressive pulmonary vascular resistance may develop at an accelerated rate in truncus, which may result in irreversible vascular disease rendering the infant inoperable at a young age. Paradoxically, symptomatic improvement of CHF with reduced pulmonary blood flow results from increasing pulmonary resistance.

CLINICAL FEATURES

Patients with truncus arteriosus usually present with severe congestive heart failure during the first few months of life. Cyanosis is usually not clinically visible.[22] The severity of congestive heart failure not only is dependent on pulmonary blood flow volume, but it also may be aggravated by truncal valve regurgitation.

Tachypnea, decreased feeding, and irritability may be the first clinical symptoms. Although the symptoms usually occur within the first few days of life, they may be delayed up to several weeks, secondary to the delay in the decrease in pulmonary vascular resistance. Clinically, an infant with truncus arteriosus will present similarly to a patient with ventricular septal defect and ductus arteriosus or one with an aortopulmonary artery window and ventricular septal defect. Frequently, a systolic murmur is heard at the left sternal border; this murmur is usually holosystolic. This is accompanied by an ejection click and followed by a single second heart sound. Occasionally, an early diastolic murmur may be present from truncal valve regurgitation, or a continuous murmur may be present, if there is a pressure gradient from the truncal root to the branching of the pulmonary arteries or artery. Palpable peripheral pulses may become collapsing and sharp in contour secondary to the pulmonary artery run-off.

The electrocardiogram usually shows biventricular hypertrophy. Isolated right or left ventricular hypertrophy is less common.

The chest roentgenogram demonstrates cardiomegaly after the first day or two of life. The heart size continues to increase, as pulmonary overcirculation occurs with regression of fetal pulmonary vascular resistance. The left atrium becomes enlarged to accommodate the increased pulmonary venous return. As congestive heart failure progresses, the large pulmonary vessels become indistinct and obscured by pulmonary edema. The position of the aortic arch should always be identified. The finding of a right aortic arch with increased pulmonary vascular markings gives an extremely high probability of truncus arteriosus. If there is atresia of one of the pulmonary arteries, i.e., type A 3, then there will be asymmetry of the pulmonary vascularity, which may be associated with hypoplasia of the lung and hemithorax on the same side as the aortic arch.[22]

ECHOCARDIOGRAPHIC AND DOPPLER FEATURES

The echocardiogram evaluation usually is the first noninvasive test that can corroborate the clinical suspicion of truncus arteriosus. The long-axis parasternal view demonstrates a single great artery having a semilunar valve in continuity with the mitral valve. The truncal valve usually overrides the ventricular septum. The left atrium, in the absence of an atrial septal defect, is typically enlarged reflecting the increased pulmonary blood flow. With slight clockwise rotation of the transducer from the long axis, the origin of the left pulmonary artery is usually seen. With further rotation of the transducer into the parasternal short-axis view, both pulmonary arteries can be seen arising from the trunk. Visualization of both pulmonary arteries may be improved by sliding the transducer up one interspace.[23] In the subcostal four-chamber view, a dilated left ventricle and left atrium are again noted. In the standard subcostal long-axis view, the left ventricle and the truncus appear to originate from the left ventricle alone (Fig. 67–2). When the transducer is rotated slightly clockwise, the ventricular septum appears directed toward the truncal valve. The truncal root appears large and overrides the crest of the ventricualr septum. The left pulmonary artery can be seen originating from the posterior part of the trunk. The left atrial appendage is in close proximity to the left pulmonary artery and trunk. With counterclockwise rotation of the transducer, following the trunk toward the patient's right, both pulmonary arteries can then be seen. From the suprasternal view, the right pulmonary artery is seen in the long axis with the aorta in the short axis. In the long-axis view of the aorta, the origin of the left pulmonary artery can usually be seen above the valve. Again, the "sine qua non" of persistent truncus arteriosus

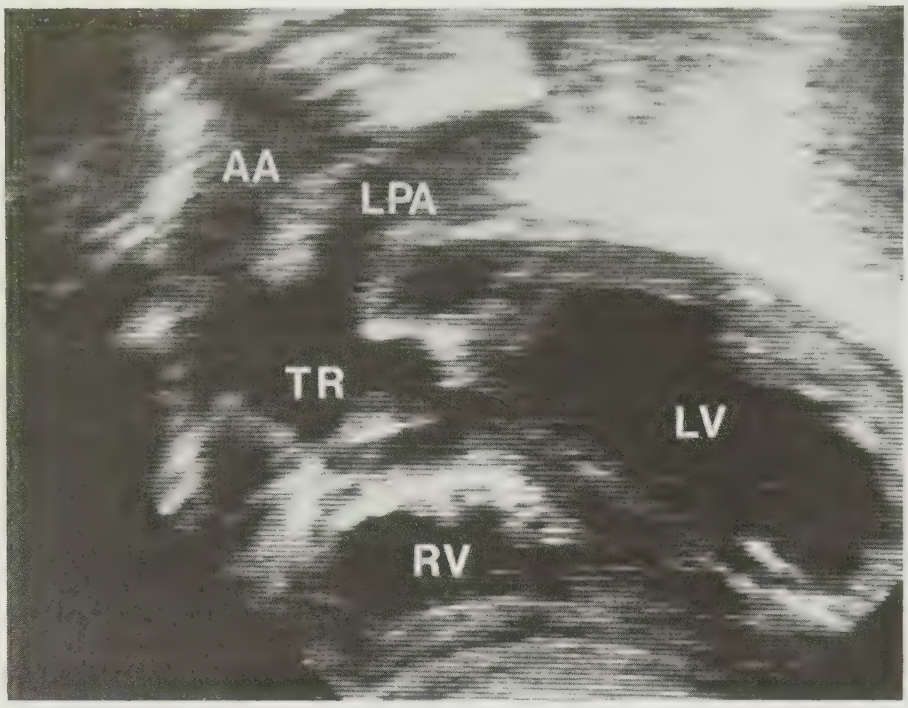

Fig. 67–2. Two-dimensional echocardiogram obtained from subcostal projection. The truncal root (TR) is located above the left ventricle (LV) and the right ventricle (RV). Consistent with the diagnosis of truncus arteriosus, the left pulmonary artery (LPA) is seen arising from the truncal root. (AA = aortic arch).

is the demonstration of the pulmonary arteries originating from a common trunk and semilunar valve. Doppler evaluation can accurately demonstrate the competency of the truncal valve. Further, color Doppler evaluation can better demonstrate the flow pattern across the truncal valve and competency of the valve. With parasternal, subcostal, and suprasternal views, differentiation of truncus arteriosus from a simple ventricular septal defect can be done with a high degree of accuracy.[23–26] However, problems may arise with differentiating truncus arteriosus from pulmonary atresia with ventricular septal defect.[24]

CARDIAC CATHETERIZATION AND ANGIOGRAPHIC FEATURES

Cardiac catheterization and angiography have long been the most definitive evaluation of the anatomical detail and physiologic variables in truncus arteriosus. Pressures in both ventricles are systemic and pressure in the left atrium is frequently elevated due to the increased pulmonary venous return. Although one would predict that in the common trunk there would be complete mixing, with the distal pulmonary artery and aortic arch having the same oxygen saturation, in practice this usually does not occur. Frequently, the pulmonary arterial saturation may be as much as 10% less than the aortic. This is due to streamlining of blood from the right ventricle into the pulmonary trunk. Further, there may be a drop in pressure in the more distal pulmonary arteries compared to the aortic arch. Evaluation of pulmonary arterial resistance was extremely important in the past when patients were over 2 years of age prior to surgical repair. Surgery was considered not feasible if the pulmonary arteriolar resistance was greater than 8 units M^2.[27] However, the present policy of doing corrective surgery by 6 months of age should prevent the steady progression of pulmonary arteriolar resistance to the point of pulmonary vascular disease.[28–30] Patients with truncus arteriosus and single pulmonary artery still remain at a large risk for pulmonary vascular obstructive disease postoperatively.[31,32]

Truncal angiography is imperative and we prefer to use the AP and lateral views for this. The ventriculograms are probably best done in the long axial oblique and elongated right anterior oblique views. Truncal angiography can usually be done with the catheter prograde across the truncal valve (Fig. 67–3), but on rare occasions may require retrograde study. From the selective truncal angiograms, an assessment of the valve can be made. The well-

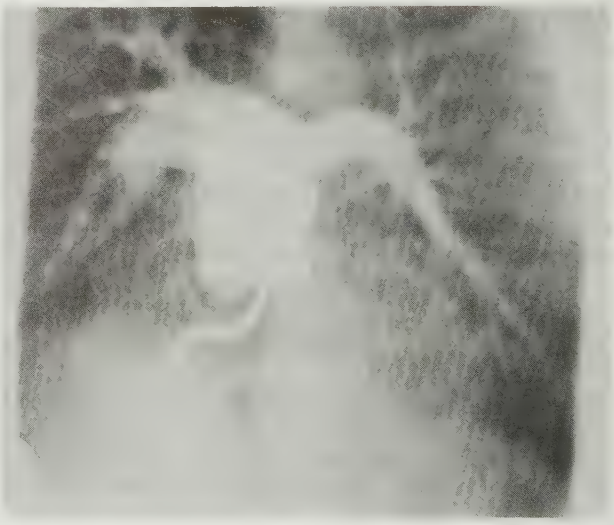

Fig. 67–3. Prograde truncal angiogram in the frontal view demonstrating truncal valve in diastole and distally the separation of the ascending aorta from the pulmonary arteries. (Angiogram courtesy of Dr. L.M. Bargeron, University of Alabama.)

formed tricuspid truncal valve can be identified using the AP and lateral views. The cusps are best seen in diastole. When the valve is bicuspid, the appearance of two valve structures is present. Dysplastic leaflets have irregular borders with poorly defined cusps. Many of these dysplastic valves will be quadricuspid. The variability of the coronary arteries can also be identified from this injection. The aortopulmonary septum with well-defined main pulmonary artery can also be visualized in this view. Usually the ventriculogram in the elongated right anterior oblique demonstrates the aortopulmonary septum well, but occasionally a truncal angiogram in the elongated right anterior oblique view may be needed to enhance the presence of an aortopulmonary septum.[11] If the aorta is noted to be significantly smaller than the pulmonary artery portion of the truncus, then an interrupted aortic arch should be expected.[33] The aortic arch is frequently right-sided and there may be a persistence of the ductus arteriosus. Anomalous subclavian artery is not unusual. Both peripheral pulmonary artery stenosis and origin of one of the pulmonary arteries from a ductus arteriosus with discontinuity of the pulmonary arteries also are not rare.[11]

The ventriculograms, perferably done from both ventricles, in both the long-axis and elongated right anterior oblique views, can delineate the anatomy and physiology of the truncus arteriosus. The long-axis view (Fig. 67–4) delineates the ventricular septal defect directly beneath the truncal valve area where the infundibular septum should be located. The left ventricular outflow tract is formed by the anterior leaflet of the mitral valve posteriorly and by the trabecular septum anteriorly. The right ventricular connection to the truncus arteriosus is bounded posteriorly by the septal structure and anteriorly by the ventriculoinfundibular fold. The elongated right anterior oblique view (Fig. 67–5) may demonstrate the right ventricular outflow to the truncus and also delineate the aortopulmonary septum of the truncus.[11] Frequently, the right ventriculogram will preferentially fill the pulmonary artery circulation. Due to the large volume of blood secondary to the mixing that occurs in truncus arteriosus, angiograms in the infant require large volumes of contrast (2 mL/kg), in order to delineate the necessary structures and mixing. Therefore, in our institution, we tend to use nonionic contrast for these studies.

Other forms of imaging truncus arteriosus may become more prevalent in the future. Magnetic resonance can accurately delineate the vessels and chambers in truncus arteriosus without the use of contrast material. Further, there is no exposure to ionizing radiation. In the future, it is possible that ultrafast computed tomography may be an imaging technique that can be used in truncus arteriosus. At the present time, magnetic resonance imaging and computed tomography are not routinely done in the work-up of truncus arteriosus.[34]

TREATMENT

The ultimate treatment for truncus arteriosus is surgical. However, the initial treatment is medical and should be aimed at cardiac decongestive therapy. In the neonate, diagnosis of classic truncus arteriosus is sufficient criteria for instigating cardiac decongestive therapy even without the signs or symptoms of congestive heart failure. As the pulmonary vascular resistance decreases, the congestive heart failure will assuredly occur. Congestive heart failure treatment consists of use of digitalis and aggressive diuretic therapy.

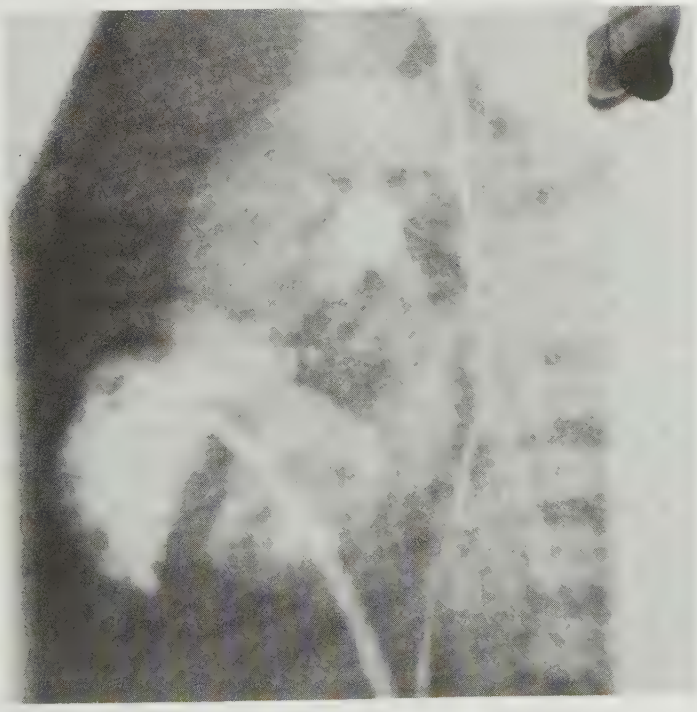

Fig. 67–4. Right ventriculogram in the long-axial view demonstrating ventricular septal defect immediately beneath the truncal valve. (Angiogram courtesy of Dr. L.M. Bargeron, University of Alabama.)

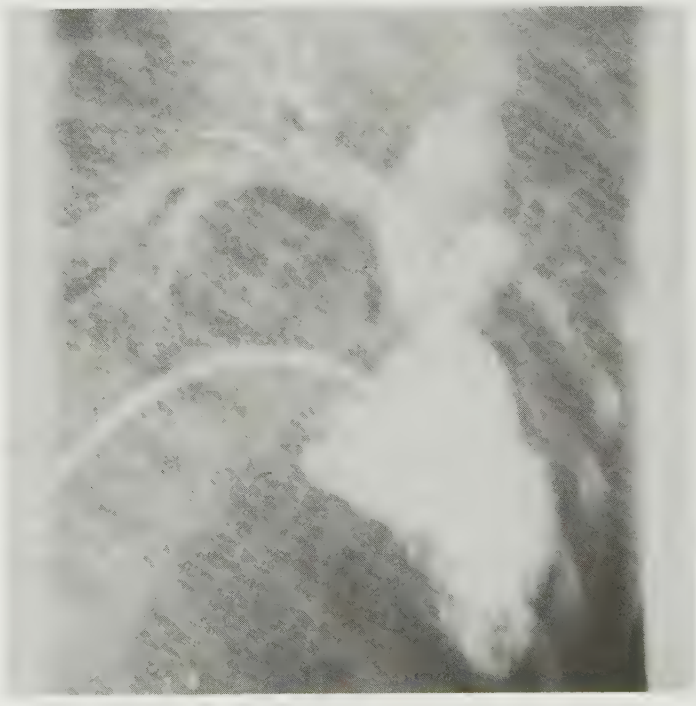

Fig. 67–5. Elongated right anterior oblique view demonstrating right ventricular outflow to truncus with distal filling of aorta and pulmonary arteries. (Angiogram courtesy of Dr. L.M. Bargeron, University of Alabama.)

Prior to 1968, the only surgical palliation available for truncus arteriosus was pulmonary artery banding. The evolvement of radical corrective surgery for truncus arteriosus began with Lillehei et al. when it was demonstrated that the right ventricular outflow tract in tetralogy of Fallot could be enlarged with a patch.[35] In 1965, Rastelli used an artificial, valveless pulmonary artery conduit made of pericardium for pulmonary atresia.[36] Rastelli et al., in 1967, experimentally used an ascending aorta and aortic valve homograft to establish right-ventricular–to–pulmonary-artery flow.[37] In 1968, McGoon et al. used this method for the first successful correction of truncus arteriosus.[38] Later it was found that homografts tended to calcify and become stenotic. In 1973, Malm used an artificial pulmonary trunk of Dacron containing a valve xenograft.[39]

The surgery for primary repair of truncus is based on the original techniques of Rastelli and McGoon.[30,36] The pulmonary trunk is initially incised and separated from the truncus artery. The suture line in the truncus artery is completed and the distal end of the pulmonary trunk is prepared for the conduit. A vertical right ventriculotomy is made to expose the VSD. The VSD is closed by suturing a Dacron patch to the edges of the septal defect in such a way to incorporate the truncal valve into the left ventricular outflow tract. The aortic homograft valved conduit is then interposed between the right ventriculotomy and the pulmonary trunk. Some refinements in technique have been used for repair of types 2 and 3 of Collett and Edwards, such as complete division of the trunk root with primary closure with absorbable suture and isolation of the pulmonary orifice as a button to which the valved conduit is attached.[40,41] Some authors advocate the use of valveless conduits in neonates as a primary repair.[42] Replacement of the conduit is later necessary because of body growth, or pseudointima proliferation. Early primary repair should be considered a two-stage procedure with subsequent conduit replacement.

Primary repair in young infants without fixed alveolar resistance has been achieved by Ebert with the remarkably low mortality rate of 11%. There were no deaths in Ebert's 55 patients requiring conduit replacement.[28]

Twelve percent of patients with truncus arteriosus have a single pulmonary artery. Modified criteria for determining operability are necessary for this subgroup.[31] In truncus with two pulmonary arteries in parallel, the total pulmonary arteriolar resistance is expressed by the following equation:

$$\frac{1}{R_T} = \frac{1}{R_L} + \frac{1}{R_R}$$

in which R_T is the total pulmonary resistance; R_L is the left lung resistance, and R_R is the right lung resistance. This calculation of total pulmonary resistance correlates well with histological arteriolar changes. However, in truncus with unilateral absence of a pulmonary artery the following hemodynamic situation would apply:

$$\frac{1}{R_T} = \frac{1}{R_L} \text{ or } \frac{1}{R_R}$$

By assuming the entire pulmonary blood flow is through the lung with the connected pulmonary artery, Mair[27] postulates that the R_L or R_R should be halved. The calculated resistance by this method correlates well with histologic arteriolar changes in patients with unilateral absence of a pulmonary artery and truncus.

After diagnosis of truncus arteriosus, the challenge to the cardiologist is to determine the optimum time for surgical intervention. Stabilization of the hemodynamics and maturation and growth of the infant need to be balanced with the potential of rapid cardiac deterioration and/or potential for pulmonary hypertension. By surgically correcting infants at 6 months or earlier, persistent pulmonary hypertension can be prevented. The exception to this may be in those infants with a single pulmonary artery; however, the only chance for these infants to avoid persistent pulmonary hypertension is surgery under 6 months of age.[31] Not only is the cardiologist challenged by timing the corrective surgery initially, close followup and deliberation is necessary to determine the optimal timing for conduit replacement.

The continued advances in surgical therapy for truncus arteriosus in the last two decades have been exciting. A lesion previously considered inoperable now is surgically correctable. The refinements in the diagnosis and treatment of truncus arteriosus continues to make treatment of this lesion a most interesting challenge to the physician.

CHAPTER 68

Ebstein's Anomaly of the Tricuspid Valve

Co-burn J Porter

On June 28, 1864, a 19-year-old laborer was admitted to All Saints' Hospital in Breslau, Poland because of shortness of breath and palpitations.[1] He was quite emaciated, had pronounced cyanosis and marked jugular venous pulsations, and was suspected of having congenital heart disease. Without any treatment, he died a week later, and shortly thereafter a postmortem examination was performed by Dr. Wilhelm Ebstein. Doctor Ebstein found three cardiac abnormalities: 1) a severe malformation of the tricuspid valve, 2) absence of a thebesian valve, and 3) a patent foramen ovale. He recognized that the most important abnormality was that of the tricuspid valve. He published his case report in the *Archiv fur Anatomie, Physiologie und wissenschaftliche Medicin* of January 12, 1866,[2] emphasizing the circulatory disturbances caused by the abnormal tricuspid valve and explaining the genesis of the systolic and diastolic murmurs during life. In 1900, William G. MacCallum, an assistant professor of pathology at Johns Hopkins University, described a museum specimen that appeared to be identical to Ebstein's case: this was the first case to appear in the English literature.[3] In 1927, Alfred Arnstein published the fourteenth case report and concluded that this abnormality of the tricuspid valve should be called ''Ebsteinsche Krankheit'' (Ebstein's disease).[4]

DEFINITION OF LESION

Ebstein's anomaly is a congenital cardiac abnormality in which the tricuspid valve leaflets do not attach normally to the tricuspid valve annulus. The effective tricuspid valve orifice is displaced apically into the right ventricle, near the junction of the inlet and trabecular parts of the right ventricle. There are additional abnormalities of the atrioventricular sulcus, valve leaflet tissue, and structure and internal morphology of the right ventricle. Ebstein's anomaly affects almost exclusively the tricuspid valve (very rare cases of the mitral valve), which is normally the right atrioventricular valve, but the left atrioventricular valve can be affected in cases of congenitally corrected transposition.

ANATOMY[5]

Displacement of Tricuspid Valve Leaflets

Only the septal and posterior (inferior) leaflet attachments are displaced (Fig. 68–1). The commissure between the two leaflets is the point of maximum displacement and is at the posterior border of the ventricular septum. These two leaflets are quite dysplastic and of variable size. In the majority of hearts, the leaflets are truly displaced, and in a smaller percentage the leaflets are extensively adherent to the ventricular wall.

Anterior Leaflet

The anterior leaflet is not displaced but is enlarged (''sail-like'') and has abnormal fibrous strands running through it. This leaflet is abnormally attached posteroinferiorly to the ledge between the inlet and the trabecular portions of the right ventricle.

Atria and Atrioventricular Sulcus

The right atrium is usually quite dilated, and the right atrioventricular junction is enlarged circumferentially. The valve of the inferior vena cava (eustachian valve) is often very prominent.

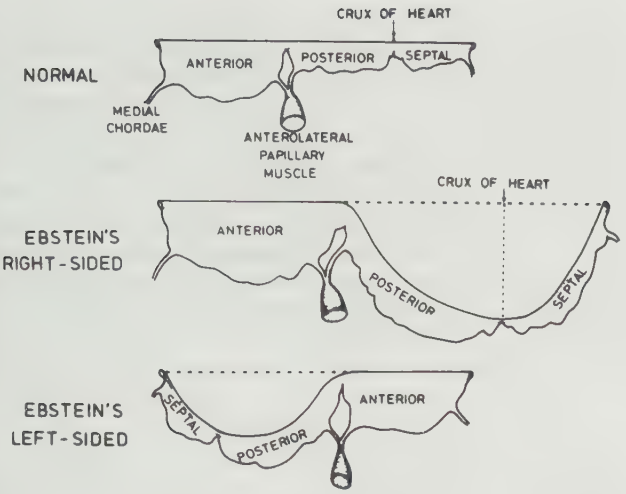

Fig. 68–1. Tricuspid valve opened out to show leaflets in a single plane. In both right-sided and left-sided Ebstein's anomaly, point of maximum displacement is at commissure between septal and posterior leaflets. This commissure is normally situated at crux of heart. (From Anderson, K.R., et al.: Morphologic spectrum of Ebstein's anomaly of the heart: a review. Mayo Clin. Proc., *54*:174, 1979. By permission of Mayo Foundation.)

Right Ventricle

Because of the displaced tricuspid valve, the right ventricle is divided into two parts: the inlet portion (''atrialized'' ventricle) and the trabecular and outlet portions (functional ventricle). The atrialized ventricle usually has a thinner wall than the functional right ventricle. Pathologic studies in patients with dilation of the functional right ventricle have shown a thinning of the wall, with an absolute decrease in the number of myocardial fibers. Uhl's anomaly of the right ventricle may closely resemble Ebstein's anomaly, but there is no abnormality of the tricuspid valve in the former.[6]

Imperforate Ebstein's Anomaly

Approximately 10% of hearts with Ebstein's anomaly have an imperforate tricuspid valve. In this situation, the anterior leaflet totally blocks the atrialized ventricle from the functional portion. This has been referred to also as ''Ebstein's anomaly with tricuspid atresia.''

Coronary Arteries

In the usual form of Ebstein's anomaly, the coronary arteries are normal except for the fact that the right coronary artery may be displaced superiorly and posteriorly (coursing in the atrioventricular sulcus) because of an aneurysmally dilated atrialized ventricle.

Conduction Tissue

Limited studies have been performed on the specialized conduction tissue in hearts with Ebstein's anomaly.[5,7] The sinoatrial node appears to be normally positioned as is the proximal part of the atrioventricular conduction tissue. However, various abnormalities of the right bundle branch have been reported. It may a) be located superficially in the subendocardium of the atrialized ventricle; b) fan out in a fashion similar to the normal left bundle branch; c) give off small communications high to the right side of the septum; and d) be encased in dense, fibroelastic tissue. In addition, accessory atrioventricular pathways have been reported bridging the right atrioventricular sulcus and giving rise to the Wolff-Parkinson-White pattern on the electrocardiogram.[7] During normal embryogenesis, the AV valve leaflets and tensor apparatus are formed by delamination of the inner layers of the inlet zone of the ventricles. In Ebstein's anomaly, the AV junction is juxtaposed to the inlet zone, such that abnormal delamination and displacement of the junction of the inlet and trabecular septum could arrest the development of the right sided AV annulus.

Associated Anomalies

A patent foramen ovale or true atrial septal defect is found in virtually all patients with Ebstein's anomaly. Pulmonary stenosis or atresia is found in a small perecentage of patients. A ventricular septal defect is found rarely.

Left Ventricle

Histology of the left ventricle in patients age 9 to 40 years with Ebstein's anomaly has shown variable large areas of fibrosis, hypertrophy, and nonspecific dysplasia.[8] All of these findings are consistent with the left ventricular dysfunction seen at catheterization or on two-dimensional echocardiography.

EMBRYOLOGY

The tricuspid valve leaflets and chordae are formed from the interior of the embryonic right ventricular myocardium by undermining the inlet zone of the ventricular wall (''delamination'').[9] Initially muscular, the leaflets and chordae later become fibrous. The anterior leaflet is formed very early in development, but the posterior and septal leaflets are formed much later (in the 3- to 4-month-old fetus) (Fig. 68–2). In Ebstein's anomaly, the inferior and septal leaflets insert at the junction of the inlet and trabecular portions, suggesting an arrest in the delamination process. The

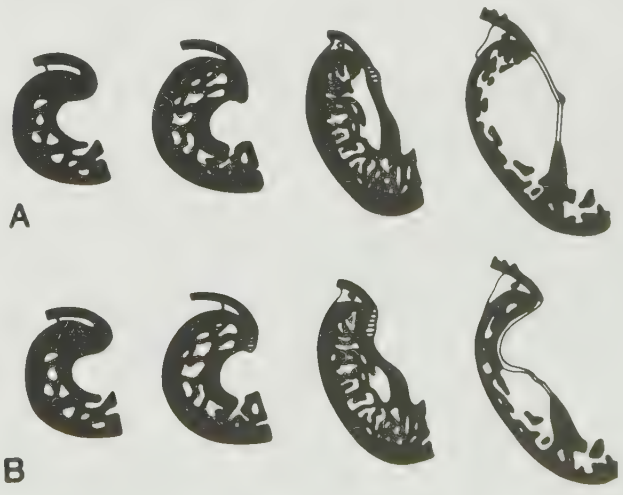

Fig. 68–2. (A) Formation of normal atrioventricular valve cusp. (B) Ebstein's anomaly. (From Van Mierop, L.H.S., and Gessner, I.H.: Pathogenetic mechanisms in congenital cardiovascular malformations. Prog. Cardiovasc. Dis., *15*:67, 1972. By permission of Grune & Stratton.)

anterior leaflet is also formed from tissue at the junction of the inlet and trabecular zones. In the imperforate or highly stenotic types of Ebstein's anomaly, the anterior leaflet forms the dividing membrane and may be entirely muscular.

EPIDEMIOLOGY, ETIOLOGY, AND GENETICS

Ebstein's anomaly is a relatively rare congenital heart defect, found in 1 of 1000 autopsies of patients with congenital cardiac lesions[10]; the suggested incidence figure is 1 per 210,000 live births.[11] This defect is believed to constitute less than 1% of all congenital heart defects.[11] Of 2251 infants with cardiac disease who qualified for entry into the New England Regional Infant Cardiac Program, 13 had Ebstein's anomaly (0.5%).[12] There are equal numbers of males and females with Ebstein's disease.[13,14] Lithium has been implicated as a possible etiologic agent.[15] The majority of instances are sporadic, but familial cases have been reported. There is a difference of opinion as to whether there is a hereditary basis for transmission.[16,17]

PATHOPHYSIOLOGY

The broad spectrum of pathologic findings in Ebstein's anomaly produces the variable hemodynamic manifestations. The pathophysiologic changes are related to several factors: a) degree of tricuspid valve incompetence or, more rarely, stenosis; b) presence of a true atrial septal defect or patent foramen ovale; c) degree of right ventricular dysfunction; and d) amount of left ventricular dysfunction. To a lesser degree, the pathologic substrates predisposing to tachyarrhythmias produce an additional dimension contributing to the pathophysiology.

Because of tricuspid valve incompetence or stenosis, there is a reduced volume of blood in the right ventricle to be ejected into the pulmonary circulation and a larger volume of blood in the right atrium. This larger volume of blood in the right atrium contributes to right atrial distention and, in the presence of an atrial septal defect or patent foramen ovale, results in right-to-left shunting at the atrial level. In addition, because of ventricular dysfunction in an already small, functional right ventricle, during ventricular systole pulmonary forward flow can be impaired leading to further regurgitation and right-to-left shunting; during ventricular diastole true right ventricular filling can be impaired because of reduced ventricular compliance. With increasing amounts of right-to-left shunting, there will be increasing cyanosis and higher levels of polycythemia. In patients with Ebstein's anomaly, decreased functional capacity (measured by New York Heart Association [NYHA] classification) was related to a) a small functional right ventricle and large atrialized right ventricle, b) valve leaflet abnormalities such as extreme displacement or absence of the septal leaflet and degree of displacement or tethering of the anterior leaflet, and c) the aneurysmal dilation of the right ventricular outflow tract.[18]

Although the primary focus in patients with Ebstein's anomaly has been on right-sided structures, there have been an increasing number of reports of left-sided abnormalities, specifically in left ventricular size, shape, and function,[8,19,20] primarily due to diastolic bowing of the interventricular septum toward the left ventricular free wall. Radionuclide scans and cineangiograms have shown impaired left ventricular function at rest in unoperated patients.[8,19,20] With exercise, most unoperated patients show an appropriate increase in left ventricular ejection fraction due to a reduced end-systolic volume and unchanged end-diastolic volume.[20]

The infant with Ebstein's anomaly poses an additional problem. In all infants immediately after birth, the pulmonary resistance is elevated and decreases fairly rapidly in the first days of life. However, in the infant with Ebstein's anomaly the combination of tricuspid regurgitation and elevated pulmonary resistance can lead to right heart failure and a significant right-to-left shunt. These infants can be quite cyanotic and present a therapeutic dilemma until the pulmonary resistance begins to decrease and the pulmonary flow increases.

CLINICAL FEATURES

History

It is usual for a patient with Ebstein's anomaly to present in the newborn period. In general, these infants have severe cyanosis as the predominant sign; less frequently they may have a murmur or supraventricular tachycardia. Beyond the newborn period the presentation is more variable (Table 68–1). Although some older patients are without symptoms, the majority have dyspnea (or fatigability), cyanosis, or palpitations (or true tachycardia).[13,14,21,22] In these patients, low arterial oxygen tensions stimulate the carotid bodies and cause increased ventilation. In addition, inadequate perfusion of exercising muscles may provoke reflex ventilatory stimulation. Palpitations are caused by single or multiple premature atrial or ventricular extrasystoles, or both; prolonged palpitations are due to paroxysmal tachyarrhythmias, generally supraventricular in origin, but occasionally ventricular. Palpitations in a cyanotic child should raise the possibility of Ebstein's anomaly.

Physical Findings

At the Mayo Clinic, many older children and adults have been referred for evaluation. In our series, the mean age at diagnosis

From Giuliani, E.R., Fuster, V., Brandenburg, R.O., and Mair, D.D.: Ebstein's anomaly: the clinical features and natural history of Ebstein's anomaly of the tricuspid valve. Mayo Clin. Proc., *54*:163, 1979. By permission of Mayo Foundation.

was 14.1 years (Fig. 68–3)[14]; the oldest patient presented with severe tricuspid incompetence and congestive heart failure at 79 years.[23] Growth and development are generally normal. Cyanosis and digital clubbing are present in patients with associated right-to-left shunt. Many have an unusual facial coloration described as "violaceous hue," "flushed," "florid," "red cheeked," or "malar flush."[22] Usually, these patients have at least mild polycythemia. Asymmetry of the chest with prominence of the left side is a frequent finding; however, an overactive precordium is rarely found. Arterial and venous pulsations are normal usually, even in the presence of tricuspid insufficiency. The jugular venous pulsations may not have the large "V" wave because of poor transmission of the venous pulse wave in the presence of a dilated, compliant right atrium.

Generally, auscultation is one of the first findings alerting one to the diagnosis of Ebstein's anomaly. There is a multiplicity of sounds and murmurs that are so characteristic as to "stand out" even to the untrained ear. Occasionally the heart sounds are soft, but usually they are of normal intensity. The first heart sound is widely split, due to delayed closure of the abnormal tricuspid valve. The second heart sound is also widely and persistently split due to late closure of the pulmonic valve, believed to be due to right bundle branch block. Ventricular filling sounds (S_3 or S_4, or both) are common and contribute to the multiplicity of heart sounds. Because of so many heart sounds, one perceives a "gallop" or "quadruple" rhythm or cadence quality, which is fairly easily recognized. A holosystolic murmur (grade 2 to 4 over 6) is found along the left sternal border—a manifestation of tricuspid regurgitation. Frequently, in the same location, there are diastolic murmurs of low intensity as a result of anterograde flow across the tricuspid valve. All murmurs tend to vary with respiration, increasing with inspiration.

Electrocardiogram

The electrocardiogram is usually abnormal and helps to confirm the clinical diagnosis (Table 68–1, Fig. 68–4). Although sinus rhythm is usually present, atrial fibrillation can be found in a few patients. In any large series, one-third to one-half of the patients have prolonged P-R intervals, and one-fourth to three-fourths meet criteria for right atrial enlargement ("himalayan" P waves).[14,22] The QRS axis in the frontal plane occasionally shows right-axis deviation. Most patients have right bundle branch block and many have low-voltage QRS complexes in the right precordial leads. Right ventricular hypertrophy is extremely uncommon.

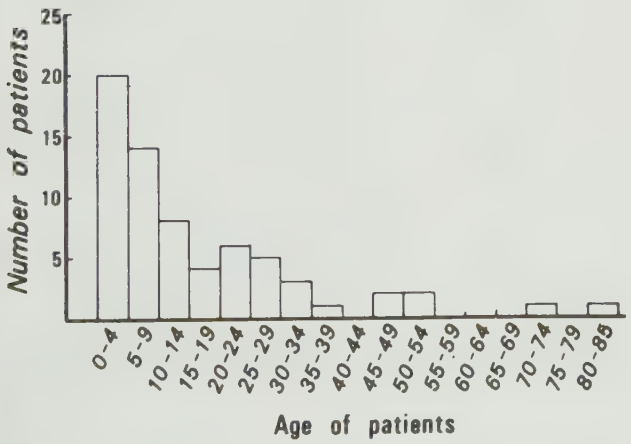

Fig. 68–3. Age distribution of 67 patients with proven Ebstein's anomaly of tricuspid valve. Age at time of diagnosis is given. (From Giuliani, E.R., Fuster, V., Brandenburg, R.O., and Mair, D.D.: Ebstein's anomaly: the clinical features and natural history of Ebstein's anomaly of the tricuspid valve. Mayo Clin. Proc., *54*:163, 1979. By permission of Mayo Foundation.)

From 4 to 26% of patients with Ebstein's anomaly have the Wolff-Parkinson-White pattern, virtually always type B (Fig. 68–5).[14,22,24] This is due to an accessory atrioventricular connection. Several resting or exercise electrocardiograms or 24-hour ambulatory electrocardiograms may have to be examined to find the characteristic electrocardiographic pattern. Occasionally, the pattern is transient or intermittent.[25–27] The absence of anterograde pre-excitation does not indicate that the accessory connection is no longer present or that the patient is no longer susceptible to tachycardia. The patient may still have retrograde conduction allowing for reentry tachycardia to occur. Patients with Ebstein's anomaly, a normal P-R interval, and a delta wave may have Wolff-Parkinson-White, but extremely delayed conduction through the right atrium; if there is coexistent left-axis deviation, there may be an accessory nodoventricular connection (Mahaim fiber).[28]

Arrhythmias in the unoperated patient with Ebstein's anomaly are common.[29] Of 52 patients who underwent evaluation for surgery at the Mayo Clinic, 41 (79%) had either documented arrhythmias or history of palpitation, near syncope, or syncope. Of 34 patients with electrocardiographic documentation of one or more arrhythmias, 18 had paroxysmal supraventricular tachycardia, 10 had paroxysmal atrial fibrillation or flutter, 13 had ventricular arrhythmias (7 frequent ventricular premature complexes and 5 nonsustained ventricular tachycardia), and 3 had atrioventricular block (2 complete AV block and 1 Mobitz II second degree). Of the 13 patients with ventricular arrhythmias, 5 had, in addition, paroxysmal supraventricular tachycardia, 4 had paroxysmal atrial fibrillation or flutter, and 1 had complete AV block. The patients with arrhythmias or symptoms compatible with arrhythmia were significantly older than patients without symptoms or arrhythmias.

Chest Radiograph

The cardiac size may vary from near normal to the extreme cardiomegaly that is fairly typical of Ebstein's anomaly. The typical contour is found in most cases and consists of a "balloon-shaped" enlarged heart with a narrow base reminiscent of that seen with a pericardial effusion (Fig. 68–6). The dilated right atrium is responsible for most of the enlarged cardiac silhouette. In the PA view, the right atrium produces a significant convexity of the right heart border, whereas in the lateral view the right atrium may fill the entire retrosternal space. The convex left heart border is due primarily to dilation of the right ventricular outflow tract. The convexities of both left and right heart borders produce a rather characteristic "globular" cardiac silhouette. In cyanotic patients with a right-to-left shunt, the pulmonary vascularity is decreased; otherwise it is usually normal. In the newborn period it is not unusual for the heart to have normal size and shape. This may confuse the clinical diagnosis.

Echocardiography

At the Mayo Clinic, echocardiography has become the procedure of choice for the diagnosis and preoperative assessment of

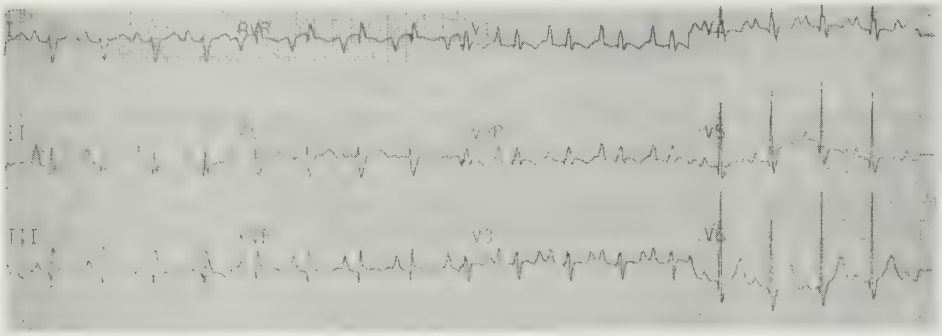

Fig. 68–4. ECG from 15-year-old boy with Ebstein's anomaly. Note prominent P wave, prolonged AV conduction, and delay in right ventricular conduction. (From Driscoll, D.J., Fuster, V., and McGoon, D.C.: Congenital heart disease in adolescents and adults. I. Ebstein's anomaly of the tricuspid valve. *In* Cardiology: Fundamentals and Practice. Edited by R.O. Brandenburg, V. Fuster, E.R. Giuliani, and D.C. McGoon. Chicago, Year Book Publishers, 1987, pp. 1459–1469. By permission of Mayo Foundation.)

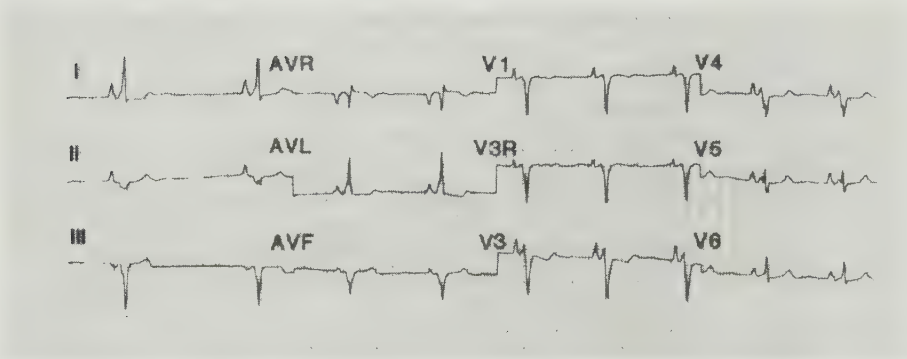

Fig. 68–5. Electrocardiogram of 13-year-old girl with Ebstein's anomaly and pre-excitation shows evidence of right atrial enlargement and Wolff-Parkinson-White syndrome (type B with delta waves in leads I, AVL, and V4-6). (From Porter, C.J., and Holmes, D.R.: Preexcitation syndromes associated with congenital heart disease. *In* Cardiac Preexcitation Syndromes. Edited by D.G. Benditt and D.W. Benson. Boston, Martinus Nijhoff, 1986, pp. 289–301. By permission of the publisher.)

Fig. 68–6. Chest radiograph from an 11-year-old male shows a narrow base and moderate generalized cardiomegaly. The prominent right heart border is a result of the enlarged right atrium. Dilatation of the right ventricular outflow tract produces displacement of the upper left cardiac border. The pulmonary vascular markings are normal to somewhat decreased.

patients with Ebstein's anomaly. Initially only M-mode echocardiography was available for evaluation. Features of Ebstein's anomaly found with M-mode echocardiography included: a) ability to record the anterior tricuspid leaflet farther to the left of the left sternal border than in normals and b) abnormally prolonged interval between the closure points of the tricuspid and mitral valve echoes.[30] The most reliable single M-mode criterion is the relationship of mitral valve closure to tricuspid valve closure. Normally the tricuspid valve closes within 30 to 50 milliseconds after the mitral valve.[30,31] If the tricuspid closure is more than 50 milliseconds after the valve closure, the diagnosis of Ebstein's anomaly should be strongly considered (Fig. 68–7).[14] Abnormal activation of the right ventricle (i.e., right bundle branch block) is not responsible for the prolonged mitral-tricuspid closure interval.[32]

With the advent of two-dimensional echocardiography, the diagnosis of Ebstein's anomaly has become easier to make.[33–35] Real-time two-dimensional imaging has provided several reliable features found in patients with Ebstein's anomaly (Fig. 68–8): a) apical displacement of the septal leaflet of the tricuspid valve (virtually all patients), b) displacement of the anterior leaflet (uncommon), c) leaflet tethering to subjacent myocardium of either the septal or the large anterior leaflet (specific for Ebstein's), d) absence of septal tricuspid leaflet (uncommon), e) elongation of the anterior leaflet (characteristic of Ebstein's), f) increased tricuspid valve annulus dimension (most), g) increased total right ventricular cavity size (nonspecific), h) aneurysmally dilated right ventricular outflow tract (infrequent), i) exaggerated tricuspid valve motion (virtually all), j) reduced left ventricular contractility (occasionally), and k) mitral valve prolapse (infrequent).[18]

In normal hearts the septal leaflet of the tricuspid valve inserts more apically than the septal portion of the anterior mitral leaflet. Therefore, certain criteria had to be developed to characterize

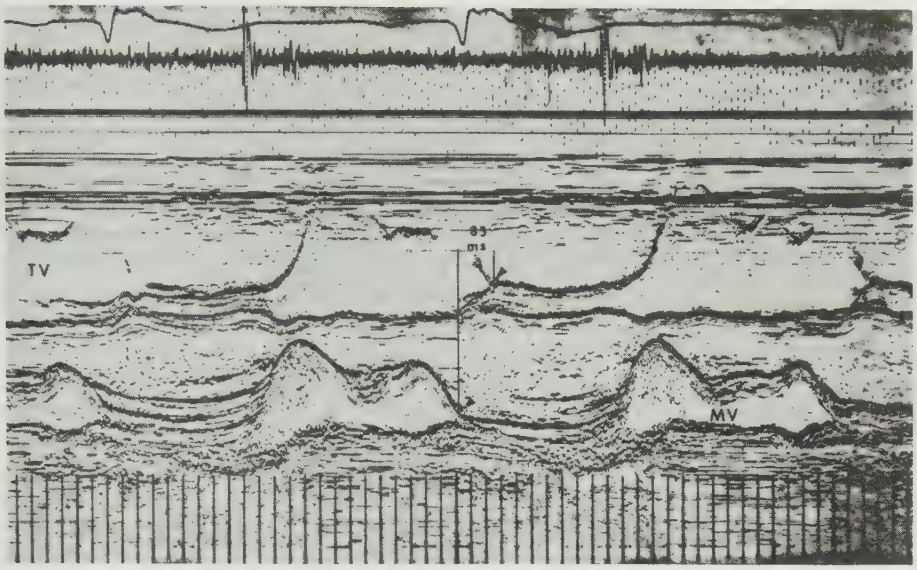

Fig. 68–7. Echocardiogram in cyanotic 29-year-old man with Ebstein's anomaly and cardiac failure. Note 85-ms interval between mitral and tricuspid valve closure. *TV* = tricuspid valve; *MV* = mitral valve. (From Giuliani, E.R., Fuster, V., Brandenburg, R.O., and Mair, D.D.: Ebstein's anomaly: the clinical features and natural history of Ebstein's anomaly of the tricuspid valve. Mayo Clin. Proc., *54*:163, 1979. By permission of Mayo Foundation.)

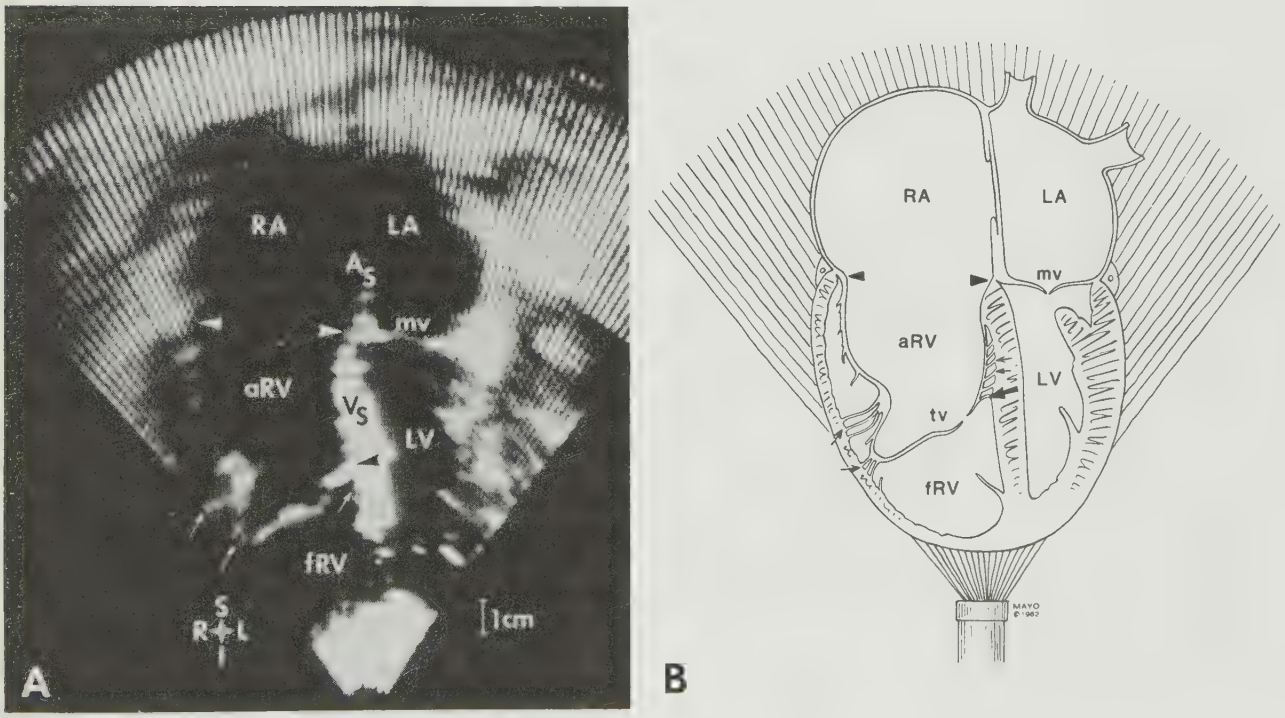

Fig. 68–8. Two-dimensional echocardiogram, typical four-chamber view, in a patient with Ebstein's anomaly. Note that septal tricuspid valve (*tv*) leaflet was displaced into right ventricle (*large black arrow*) and thus formed atrialized right ventricle (*aRV*). Anterior tricuspid leaflet was elongated, and it originated from true tricuspid annulus (*top arrowheads*). Both leaflets were tethered to underlying myocardium (*small arrows*). Tricuspid annulus and right atrium (RA) were dilated. *AS* = atrial septum; *fRV* = functional right ventricle; *I* = inferior; *L* = left; *LA* = left atrium; *LV* = left ventricle; *mv* = mitral valve; *R* = right; *S* = superior. (Part A, from Shiina, A., et al.: Two-dimensional echocardiographic-surgical correlation in Ebstein's anomaly: preoperative determination of patients requiring tricuspid valve plication vs replacement. Circulation, *68*:534, 1983. By permission of the American Heart Association. Part B, from Shiina, A., et al.: Two-dimensional echocardiographic spectrum of Ebstein's anomaly: detailed anatomic assessment. J. Am. Coll. Cardiol., *3*:356, 1984. By permission of the publisher.)

abnormal apical displacement of the septal leaflet of the tricuspid valve. At the Mayo Clinic, a value greater than 8 mm/m^2 of the patient's body surface area for the distance from the tricuspid annulus to the distal point of septal leafet attachment in systole is consistent with a diagnosis of Ebstein's anomaly.[18] Other authors have reported that the "critical difference" for discrimination is greater than 15 mm in children (<14 years old) and greater than 20 mm in adults.[36] By using two-dimensional echocardiographic techniques, the degree of malformation of the tricuspid valve can be determined and has been correlated with functional capacity and with whether or not surgical repair can be accomplished without the use of a prosthetic valve.[18,37,38] In addition, associated defects such as ventricular septal defects and pulmonary stenosis can be detected by two-dimensional echocardiography.

Recently Doppler and color-flow echocardiography have enhanced the noninvasive evaluation of patients with Ebstein's anomaly. Hemodynamic alterations such as valve regurgitation and intracardiac shunting can be determined in a more sensitive, qualitative fashion. With the use of these combined echocardiographic techniques, hemodynamic cardiac catheterizations are no longer necessary for patients with Ebstein's anomaly evaluated at the Mayo Clinic.

Exercise Testing

Exercise testing has become a part of the routine noninvasive studies used to evaluate patients with Ebstein's anomaly, both in the unoperated and postoperative state. Studies performed at the Mayo Clinic before and after surgery have described several interesting findings.[39,40] In unoperated patients, indices of exercise tolerance (work, exercise duration, maximal oxygen uptake) are significantly reduced. However, in postoperative patients, these indices approach the lower limit of normal. In four patients tested both preoperatively and postoperatively, three had increased exercise tolerance as measured by maximal oxygen uptake. Systemic arterial blood oxygen saturation is significantly lower at rest and during exercise in unoperated patients compared with postoperative patients. In the unoperated patient there is a significant positive correlation between maximal oxygen uptake achieved (exercise tolerance) and both rest and exercise systemic arterial oxygen saturation. The majority of unoperated patients with intact atrial septum had rest cardiac outputs (acetylene-helium rebreathing technique) below the normal mean, whereas the majority of postoperative patients had rest cardiac outputs above the normal mean. Exercise cardiac outputs were low in all of the unoperated patients with intact atrial septum and in the normal range in all the postoperative patients except one. Patients with an atrial septal defect and right-to-left shunting demonstrated excessive ventilation at rest and during exercise. In these patients a right-to-left shunt is a strong stimulus to increase ventilation.

CARDIAC CATHETERIZATION

Hemodynamics

In the early days of intracardiac investigation, it became evident that patients with Ebstein's anomaly had an increased risk for morbidity or mortality from cardiac catheterization. Some physicians stated that these patients should not undergo this procedure. However, concerns about the safety of cardiac catheterization in these patients have been lessened by modern techniques of monitoring the patient's hemodynamic status during the study and the availability of effective treatment for arrhythmias provoked by catheter manipulation.

Ebstein's anomaly is characterized by moderate elevation of the right atrial pressure, most often with a dominant V wave and steep Y descent. If, however, the right atrium is massively dilated, the atrial pressure may be normal in spite of severe tricuspid regurgitation. Most often the right ventricular pressures are normal, but in some the end-diastolic pressure may be elevated. Generally the pulmonary artery pressure is normal, but it may be decreased in those with severe tricuspid regurgitation and right-to-left shunting. In those with an atrial septal defect, right-to-left shunting results in systemic arterial desaturation. Right-to-left shunting can be demonstrated also by intracardiac dye dilution curves with injection into the inferior or superior vena cava showing early appearing dye at the systemic arterial sampling site. Of historical significance is a technique of simultaneously recording the intracavitary pressure and intracardiac electrogram tracing. When a catheter with an opening and an electrode at the tip was positioned in the atrialized portion of the right ventricle, the pressure tracing recorded was atrial, but the electrogram showed ventricular activity.

Angiocardiography

Right ventricular angiocardiography is usually diagnostic of Ebstein's anomaly, except in the mildest forms. In the AP projection, contrast injection in the right ventricle will demonstrate tricuspid regurgitation, a large sail-like anterior tricuspid leaflet, and frequently a distinct notch at the inferior cardiac border to the left of the spine (Figs. 68–9 and 68–10). The notch is the site of the abnormal attachment of the displaced anterior leaflet. Frequently a "trilobed" appearance to the right-sided structures occurs as a result of contrast medium outlining the enlarged right atrium, atrialized ventricle, and the outflow portion of the functional ventricle. The presence of associated defects can be demonstrated by angiocardiography.

In a cyanotic newborn with Ebstein's anomaly, injection of contrast medium in the right ventricle may show tricuspid regurgitation and little or no contrast medium in the pulmonary artery. This suggests anatomic obstruction to the right ventricular outflow tract. However, this same finding may occur without anatomic obstruction if the pulmonary resistance is elevated. Patency of the right ventricular outflow tract should be established by other techniques, such as catheter advancement through a patent pulmonary valve or injection of contrast medium in the ductus arteriosus to show contrast medium filling the main pulmonary artery and regurgitating into the right ventricle.

Electrophysiology

Because of the occurrence of tachyarrhythmias or symptoms compatible with tachyarrhythmias in patients with Ebstein's anomaly, electrophysiologic evaluation has been performed in these patients with increasing frequency.[41,42] At the Mayo Clinic echocardiographic evaluation of anatomy has become so accurate that the only indication for a cardiac catheterization is to evaluate any arrhythmias or suspected arrhythmias. Twenty-three patients with Ebstein's anomaly underwent electrophysiologic testing at the Mayo Clinic between 1974 and 1984.[41] All patients were evaluated because of recurrent symptomatic tachycardia or as a part of their

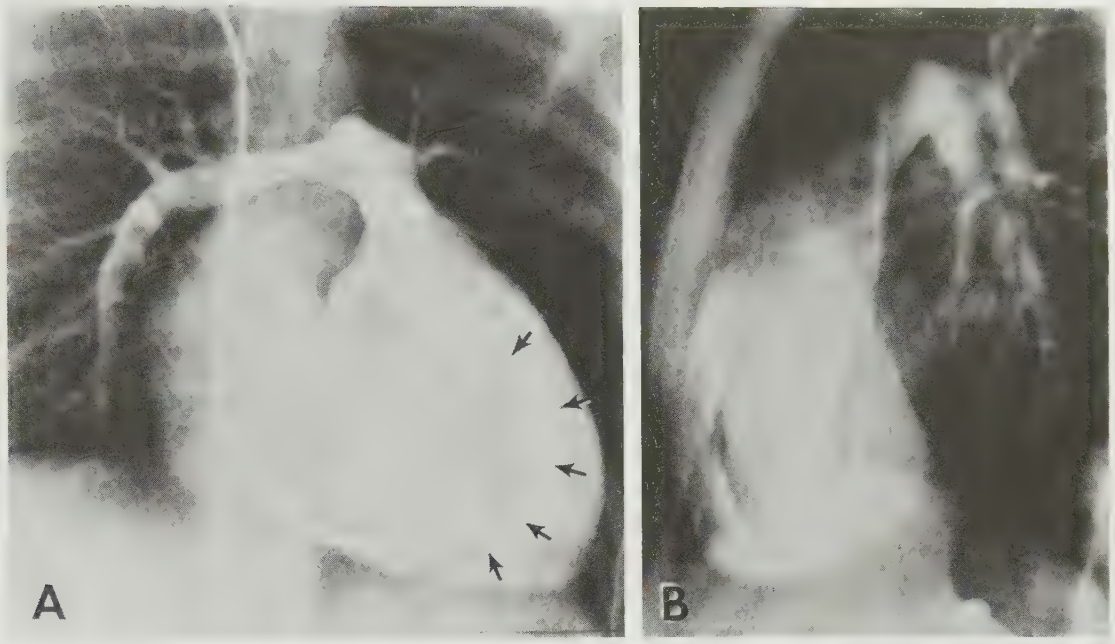

Fig. 68–9. (A) Anteroposterior and (B) lateral views of right ventriculogram in 21-year-old woman. Anteroposterior view shows large "sail-like" anterior leaflet (*arrow*) displaced well to left of spine. Severe tricuspid incompetence is evident. Lateral projection displays pronounced anterior displacement of abnormal anterior tricuspid leaflet. (From Giuliani, E.R., Fuster, V., Brandenburg, R.O., and Mair, D.D.: Ebstein's anomaly: the clinical features and natural history of Ebstein's anomaly of the tricuspid valve. Mayo Clin. Proc., *54*:163, 1979. By permission of Mayo Foundation.)

Fig. 68–10. Angiocardiogram in 25-year-old acyanotic man. Note "notch" at inferior cardiac border, well to left of spine. (From Giuliani, E.R., Fuster, V., Brandenburg, R.O., and Mair, D.D.: Ebstein's anomaly: the clinical features and natural history of Ebstein's anomaly of the tricuspid valve. Mayo Clin. Proc., *54*:163, 1979. By permission of Mayo Foundation.)

preoperative assessment before tricuspid valvuloplasty or valve replacement. Of the 23 patients, 12 had both Ebstein's anomaly and pre-excitation and underwent valve surgery with ablation of the accessory atrioventricular connections. Eleven of these 12 patients had a history of tachycardia before the electrophysiologic study.

In the patients with pre-excitation studied preoperatively at the Mayo Clinic, the average PA interval was 37 msec (range, 15 to 63 msec) and the average AH interval was 86 msec (range, 70 to 120 msec); half of the patients had enhanced atrioventricular nodal conduction and 1 patient had dual atrioventricular nodal physiology; 10 accessory pathways were right free-wall and 3 were septal; 1 patient had both a right free-wall and a septal pathway. In the series reported by Smith et al.,[42] 11 patients had a right free-wall pathway, 7 a septal pathway, and 4 had both. During study at the Mayo Clinic, six patients had one mechanism and four patients had two mechanisms for their arrhythmia. Orthodromic reciprocating tachycardia was found in seven patients: four had reentrant tachycardia only and three also had atrial flutter/fibrillation. One patient had reciprocating tachycardia due to reentry within the AV node, one had both intra-atrial reentry tachycardia and atrial flutter/fibrillation, and one had only atrial flutter. No patient had antidromic reciprocating tachycardia or evidence of an accessory nodo- or fasciculoventricular connection. No patient had induction of ventricular tachycardia. All patients in the series by Smith et al. had evidence of orthodromic reciprocating tachycardia; one also was suspected of having antidromic reciprocating tachycardia, three were believed to have an additional accessory nodoventricular or fasciculoventricular pathway, and one had inducible ventricular tachycardia.

NATURAL HISTORY

In 1974, Watson published the result of an international cooperative study of 505 cases collected from 61 centers in 28 countries.[43] Thirty-five were less than 1 year old, 403 were between 1 and 25 years, and 67 were over 25 years. Of the infants, 72% were in heart failure; but in 81% of the older patients, growth and development during infancy were said to have been average or good. Under one year of age there were 16 deaths in 35 patients for a mortality of 45.7 percent. Of the 16 deaths, 15 (94%) were due to congestive heart failure, all in patients less than 6 months old.[43] Of the patients age 1 to 25 years, 71%, and of those over age 25 years, 60%, had little or no disability and were classified as NYHA class I or II. Cardiac catheterizations had been carried out on 363 patients, with 19 cardiac arrests (13 of the 19 died). A paroxysmal tachycardia occurred during the catheterization in 90 patients (25%).

Of the 505 patients, 77 (15.2%) died from their disease. An additional 31 who had surgical treatment for Ebstein's anomaly died (54.4% surgical mortality). There is an initial high mortality from congestive heart failure in the first few months of life. Between the ages of 1 and 25 years, 50 (12.4%) of the 403 patients died from their disease. Half of the deaths were due to congestive heart failure and 20% of them were sudden deaths, presumably due to an arrhythmia. Over 25 years, there were 11 deaths (16.4%) in 67 patients.

Watson reported high mortalities with surgical treatment. For patients between ages 1 and 15 years, there was a 64% mortality for palliative procedures, such as Glenn or Blalock shunts, and a 56% mortality for definitive surgical treatment, such as insertion of a tricuspid valve prosthesis. In 15 patients over age 15 years who had definitive repair with a prosthesis, there was a 33% mortality. Thus it appeared from this early paper that surgery was not beneficial.

There have been reports of women with mild Ebstein's anomaly becoming pregnant and delivering healthy term infants.[44,45] However, others have reported fetal deaths in mothers who had more significant Ebstein's anomaly.[46,47] After surgical repair, some mothers have had uncomplicated and successful pregnancies.[48]

THERAPY

In Ebstein's anomaly there is a wide spectrum of hemodynamic abnormalities and arrhythmias that occur at various ages; therefore, no dogmatic recommendations can be made; general guidelines can be presented and each case must be judged individually. At one end of the spectrum are patients with mild anatomic abnormalities, relatively normal hemodynamics, and no symptoms, who require only observation and normal precautions to prevent bacterial endocarditis. But beyond this, the anatomic and hemodynamic abnormalities may become important enough to cause symptoms and significantly alter the patient's lifestyle. Medical therapy may be necessary for these patients, but frequently surgical therapy must be considered. The natural history of this congenital heart defect suggests that many patients do well with little or no therapy, but a certain subset requires surgical intervention.

The surgical approach to Ebstein's anomaly has evolved over the past 30 years. In the 1950s, systemic-to-pulmonary artery anastomoses were created to increase pulmonary blood flow. They were not very successful. Better results were obtained with the Glenn shunt, a superior vena cava-to-pulmonary artery connection.[49] In 1958, Hunter and Lillehei[50] tried repositioning the septal and posterior tricuspid valve leaflets, but this had no apparent success. In 1962, Barnard and Schrire[51] successfully replaced the tricuspid valve with a prosthesis; this patient was still alive and doing well 19 years after operation.[52] Reconstruction of the tricuspid valve was attempted in 1969 by Hardy and Roe.[53] At present, three approaches are available for the surgical repair of Ebstein's anomaly: 1) replacement of the valve[8,54–56] with either a mechanical or a "biological" prosthesis, 2) reconstruction of the valve,[53,57] or 3) both replacement and reconstruction.[58]

Drawing from the pioneering efforts by other surgeons, Danielson of the Mayo Clinic developed a "plastic" repair based on construction of a monocusp valve by using the enlarged anterior leaflet of the tricuspid valve (Fig. 68–11).[59] Between April 1972 and January 1982 he performed surgical repair on 42 consecutive patients with Ebstein's anomaly.[57] Of the 42 patients, 34 (81%) had a plastic repair consisting of plication of the free wall of the atrialized portion of the right ventricle, posterior tricuspid annuloplasty, and right atrial reduction. Right ventricular plication and valve replacement with a bioprosthesis were performed in six patients (14%). Two patients (5%) had a previous Glenn procedure and tricuspid valves that could not be reconstructed. In these two patients, the atrialized ventricle was plicated, and the tricuspid valve excised and not replaced. The indications for operation were functional class III or IV (NYHA), progressive cyanosis, paradoxic emboli, or uncontrollable tachyarrhythmias secondary to accessory pathways.

Mair, Danielson, and colleagues[48] provided information on an additional 30 patients. By August of 1984, a total of 72 patients with Ebstein's anomaly had undergone surgical repair at the Mayo Clinic. A plastic reconstruction of the tricuspid valve was possible in 58 patients, 81% of the entire group. In 11 patients (15%) valve replacement (10 Hancock bioprostheses) and right ventricular plication were done. In three patients (4%) with Glenn anastomoses, a Fontan-type arrangement was produced. Nine patients had accessory atrioventricular pathways ablated successfully. There were five deaths in the hospital (7%) and three late sudden deaths. Two deaths in the hospital were caused by documented ventricular fibrillation. Of those dying late, all had large hearts before surgery and significant atrial or ventricular arrhythmias before operation. Followup was available in all surviving patients for at least 2 years, with a mean of 5 years. Eighty-seven percent of the patients were in functional class I or II at followup. Significant improvements in exercise tolerance have been found in patients tested after surgery (see section on Exercise Testing in this chapter).

Because of the success of surgical treatment for certain patients with Ebstein's anomaly, selection criteria have been refined.[48] At the Mayo Clinic, surgery is recommended for the following patients: a) those whose symptoms have deteriorated to place them in NYHA class III or IV; b) those who are still in NYHA class I or II but whose cardiothoracic ratio on the plain chest film has reached 0.65 or greater; c) those with significant cyanosis (an arterial saturation of 80% or less with a hemoglobin of 16 gm or higher) and polycythemia; d) those who have suffered a paradoxical embolus, even if still in NYHA class I or II; and e) those who have an accessory atrioventricular pathway with medically uncontrollable reciprocating tachycardia. Indications for surgery

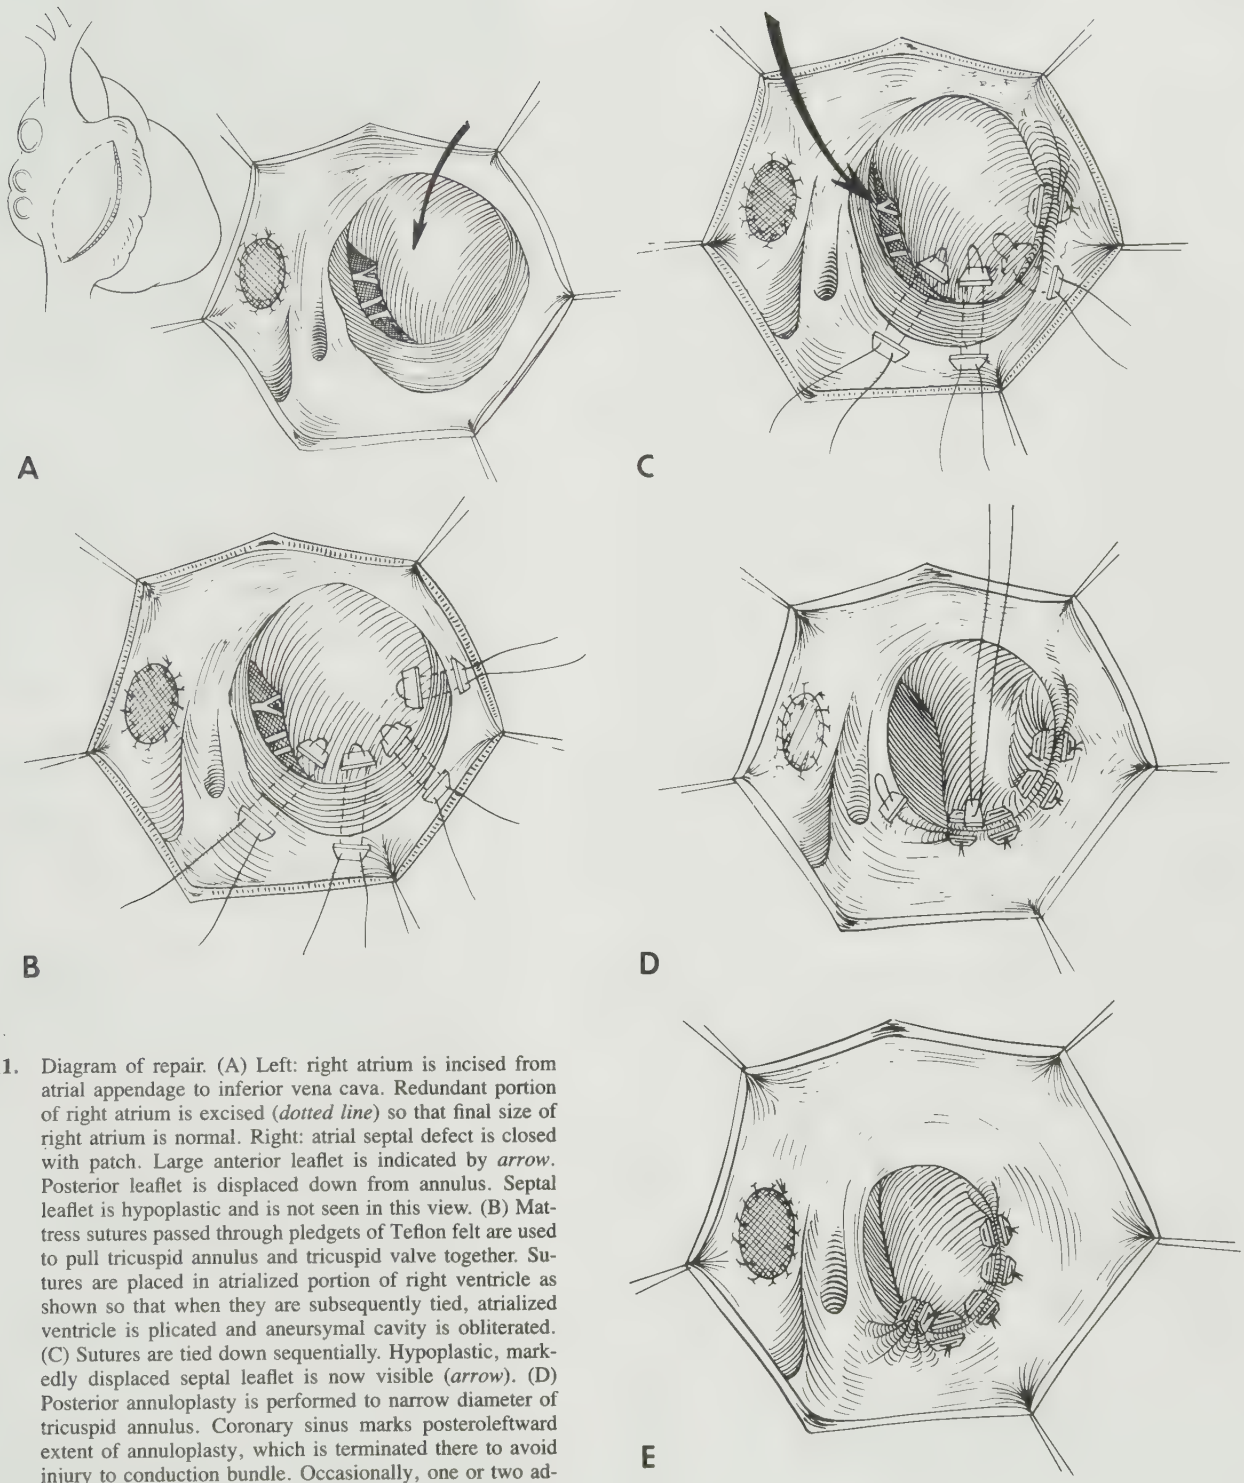

Fig. 68–11. Diagram of repair. (A) Left: right atrium is incised from atrial appendage to inferior vena cava. Redundant portion of right atrium is excised (*dotted line*) so that final size of right atrium is normal. Right: atrial septal defect is closed with patch. Large anterior leaflet is indicated by *arrow*. Posterior leaflet is displaced down from annulus. Septal leaflet is hypoplastic and is not seen in this view. (B) Mattress sutures passed through pledgets of Teflon felt are used to pull tricuspid annulus and tricuspid valve together. Sutures are placed in atrialized portion of right ventricle as shown so that when they are subsequently tied, atrialized ventricle is plicated and aneursymal cavity is obliterated. (C) Sutures are tied down sequentially. Hypoplastic, markedly displaced septal leaflet is now visible (*arrow*). (D) Posterior annuloplasty is performed to narrow diameter of tricuspid annulus. Coronary sinus marks posteroleftward extent of annuloplasty, which is terminated there to avoid injury to conduction bundle. Occasionally, one or two additional mattress sutures are required to obliterate posterior aspect of annuloplasty repair in order to render valve totally competent. Tricuspid annulus at this time will admit two or more fingers. (E) Completed repair which allows anterior leaflet to function as a monocusp valve. (Modified from Danielson, G.K., Maloney, J.D., and Devloo, R.A.E.: Surgical repair of Ebstein's anomaly. Mayo Clin. Proc., *54*:185, 1979. By permission of Mayo Foundation.)

in the infant with severe congestive heart failure or cyanosis are less clear and must be individualized after careful deliberation.

CHAPTER 69

Anomalous Pulmonary Venous Connections; Pulmonary Vein Stenosis; Atresia of the Common Pulmonary Vein

Kent E Ward
Charles E Mullins

This chapter deals with abnormalities in the pulmonary venous circulation including anomalous pulmonary venous connections (partial and total), pulmonary vein stenosis, and atresia of the common pulmonary vein. Cor triatriatum, an abnormality thought by many to have a similar embryologic origin, will not be discussed here but will be presented in Chapter 77.

ANOMALOUS PULMONARY VENOUS CONNECTIONS

Definition of Terms

We will use the term *anomalous venous connections* as proposed by Edwards[1] rather than *drainage* or *return* in order to define more clearly the anatomy of this complex of cardiac defects. Anomalous pulmonary venous drainage may occur without anomalous connection; for example, a large atrial septal defect or common atrium in which pulmonary venous blood from the right lung, although connected normally, drains directly into the right atrium. Anomalous connection, on the other hand, when defined as at least one pulmonary vein connected to the right atrium either directly or through a venous tributary, always denotes anomalous drainage. Partial anomalous pulmonary venous connection (PAPVC) occurs when one or more but not all pulmonary veins connect anomalously to the right atrium. PAPVC, which is often found in association with an atrial septal defect, usually demonstrates hemodynamic findings of increased pulmonary blood flow.

When all pulmonary veins connect anomalously to the systemic venous circulation, total anomalous pulmonary venous connection (TAPVC) is defined. TAPVC is associated with total mixing of pulmonary and systemic venous blood at the level of the right atrium; it may demonstrate increased or decreased pulmonary blood flow. If there is increased pulmonary blood flow, the patient may not have visible cyanosis; if there is reduced pulmonary blood flow (usually found with obstruction to venous return), the infant may be cyanotic. In addition, TAPVC is always associated with an interatrial communication.

Historical Perspective

The first reported case of anomalous pulmonary venous connection was by Winslow in 1739, when he described a single vein from the right upper lobe draining into the superior vena cava.[2] Sporadic case reports continued throughout the early nineteenth century, most of which emanated from the European continent. In 1868, Friedlowsky[2] reported the first case of TAPVC without associated cardiac defects in an 18-day-old infant with drainage to the left innominate vein. Brody,[2] in a classic paper published in 1942, compiled 100 previously reported cases and added 2 of his own. This paper was the first in-depth review of the subject and improved understanding of the anatomic variants and basic pathophysiology of this complex of cardiac defects. That report discussed the concepts that PAPVC usually is associated with a normal or near-normal life span, and that TAPVC is a disease process that most often leads to death in the first year of life unless a large interatrial communication exists. These observations were confirmed and enlarged by a number of investigators.[4–10] The work of Neill[11] in 1956 and Darling et al.[12] in 1957 led to a classification system based on embryologic and anatomic considerations, respectively.

The antemortem diagnosis of partial anomalous pulmonary ve-

nous connection using cardiac catheterization and angiocardiography was first reported by Dotter et al.[13] in 1949. Shortly thereafter, Friedlich and associates[14] reported their results of catheterization in 18 patients with anomalies in pulmonary venous connection; 2 of these had total anomalous pulmonary venous connection. With accurate and complete catheterization and angiocardiographic diagnoses, attempts at surgical correction ensued. In 1951, Muller[15] reported partial correction of TAPVC with the use of a closed anastomosis between the left atrial appendage and the left upper pulmonary vein. Burroughs and Kirklin,[16] using the atrial well technique, and Lewis et al.[17] using moderate hypothermia and inflow occlusion, reported successful surgical repair of TAPVC in 1956. In that same year, Cooley and Ochsner[18] performed the first successful correction of TAPVC using cardiopulmonary bypass. In the 30 years since the first report of successful surgical treatment of these abnormalities, advances in the understanding of the pathophysiology of TAPVC as well as improvements in diagnostic and operative techniques have led to a dramatic decrease in morbidity and mortality associated with these defects.

Embryology

A review of the embryologic development of the systemic and pulmonary venous systems will illuminate the nature of the many and varied abnormalities observed in patients with anomalies of pulmonary venous connection.

In the developing embryo, the primitive foregut gives rise to the lungs, larynx, and tracheo–bronchial tree. The primordial lung buds share a common vascular plexus (splanchnic plexus) with other derivatives of the foregut and, early on, drain through the paired common cardinal and umbilicovitelline veins (Fig. 69–1A). As development proceeds, this splanchnic plexus differentiates into the primitive pulmonary vascular bed and thus will drain pulmonary venous blood. This pulmonary vascular bed, however, remains in communication with the cardinal and umbilicovitelline system of veins until somewhat later in development. The right common cardinal system will later differentiate into the right horn of the sinus venosus, which will in turn give rise to the right superior vena cava and azygous vein. The left common cardinal system will become the left horn of the sinus venosus and, through further differentiation, give rise to the left superior vena cava and coronary sinus. The umbilicovitelline system will become the inferior vena cava, ductus venosus, and portal vein. At this stage of development (3 to 5 mm embryo, 25 to 27 days' gestation), there is no direct communication to the developing heart (see Fig. 69–1A).

Auer[19] and Neill[11] have contributed greatly to the understanding of early development of the pulmonary venous circulation. At 27 to 29 days' gestation, the primitive pulmonary vein can be seen as a small endothelial outgrowth from the posterior superior wall of the primordial left atrium. This vein lies directly to the left of the developing septum primum and also to the left and inferior to the left valve of the sinus venosus. At 28 to 30 days' gestation, the pulmonary vein has engaged the pulmonary portion of the splanchnic plexus, and thus begins to drain blood from this region (Fig. 69–1B). The pulmonary portion of the splanchnic plexus begins to lose connections with the cardinal and umbilicovitelline systems at this time. With further development, this separation becomes complete except for very small anastomoses between the

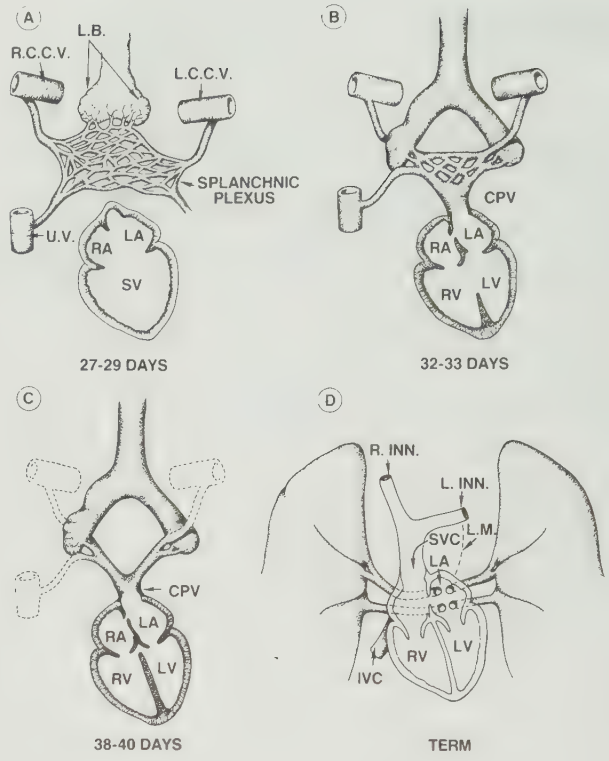

Fig. 69–1. Development of the pulmonary venous system. (A) At 27 to 29 days gestation, the primordial lung buds share a common vascular plexus (splanchnic plexus) with other derivatives of the foregut and drain through the paired right and left common cardinal (R.C.C.V., L.C.C.V.) and umbilicovitelline (U.V.) veins. A small endothelial outgrowth arises from the left atrium directly to the left of the septum primum and grows into the splanchnic plexus.' (B) This common pulmonary vein (C.P.V.) allows blood to drain directly to the heart, although at this stage it may still drain indirectly through the primitive venous connections. (C) Once the direct left atrial connection is established, the primitive pulmonary venous connections disappear. (D) Further differential growth of the left atrium leads to incorporation of individual pulmonary veins into the left atrium, usually with two veins from each lung connecting separately. CPV, common pulmonary vein; IVC, inferior vena cava; LA, left atrium; L.C.C.V., left common cardinal vein; L.B., lung buds; L.Inn., left innominate vein; L.M., Ligament of Marshall; L.A., left atrium; L.V., left ventricle; R.C.C.V., right common cardinal vein; R.Inn., right innominate vein; R.A., right atrium; R.V., right ventricle; S.V., single ventricle; S.V.C., superior vena cava. pulmonary and bronchial veins (bronchopulmonary veins). Tributaries to the pulmonary vein coalesce to form a well-defined common chamber, which is incorporated progressively into the posterior wall of the primitive left atrium (Fig. 69–1C). The final result is a left atrial chamber whose volume is made up of approximately equal parts of common pulmonary vein and primitive left atrium; the primitive left atrium includes the left atrial appendage.[20,21] This concept is important in understanding later anatomic and pathophysiologic findings in patients with TAPVC.

Complete incorporation of the common pulmonary vein into the left atrium usually results in two right and two left pulmonary veins entering through separate orifices (Fig. 69–1D). Variation

in number of pulmonary veins draining into the left atrium is common. Healy[7] found the most common variant (occurring in 24% of autopsy specimens) to be the presence of a single pulmonary vein draining either the right or left lung. The next most frequent variation occcurred in 2% of specimens and consisted of an extra pulmonary vein entering the left atrium, most commonly from the right lung. On rare occasions, a fourth or fifth vein may drain the right lung.[7] These variations in anatomy are of no hemodynamic consequence, although knowledge of their existence may be important in surgical procedures involving the left atrium.

The anatomic variations that occur in anomalous pulmonary venous connection can be readily explained by alterations in the normal sequence of embryologic events.[11,12] Thus, anomalous pulmonary venous connection directly to the right atrium occurs when the primum septum grows abnormally far to the left, leading to incorporation of the common pulmonary vein to the right. If the common pulmonary vein fails to develop, or if development proceeds early but then later the communication between the left atrium and the pulmonary vein is disrupted, primitive channels between the pulmonary plexus and the cardinal and umbilicovitelline system will persist. Drainage to the left common cardinal system results in anomalous pulmonary venous connection to either the coronary sinus or left innominate vein. Drainage to the right common cardinal system leads to pulmonary venous connection to the superior vena cava and/or azygous vein. Finally, drainage to the umbilicovitelline system results in pulmonary venous connection to the portal vein, ductus venosus, or inferior vena cava.

The timing and degree of obliteration of the common pulmonary vein/left atrial connection determine the nature of the abnormalities apparent after birth.[23] Early atresia of the common pulmonary vein, while primitive pulmonary–systemic venous connections are still present, will lead to TAPVC (Fig. 69–2B[1]). If only the right or left portion of the common pulmonary vein becomes atretic, persistence of the primitive pulmonary venous–systemic venous connection on that side would lead to PAPVC (Fig. 69–2A[1]). If atresia of the common pulmonary vein occurs after complete obliteration of the primitive pulmonary venous–systemic venous connections, then atresia of the common pulmonary vein would result. This defect is rare and is nearly always fatal because the pulmonary veins empty into a blind chamber, the only egress of pulmonary venous blood occurring through very small bronchopulmonary anastomoses.[24] This anomaly will be discussed further in the final section of this chapter. Incomplete incorporation of the common pulmonary vein into the left atrium would, according to this schema, lead to the syndrome of stenosis of the common pulmonary vein, or cor triatriatum. That this anomaly may be a spectrum of abnormalities of common pulmonary vein development is illustrated by the rare occurrence of both cor triatriatum and anomalous pulmonary venous connection in the same patient. (Cor triatriatum will be discussed in depth in Chapter 77.) Finally, abnormal incorporation of the common pulmonary vein into the left atrium may lead to abnormal numbers of pulmonary veins as described previously. Inadequate absorption of the common pulmonary vein would result in fewer than the normal number of veins, and exaggerated absorption would lead to increased numbers of pulmonary veins.

Although some authors consider stenosis of the individual pulmonary veins to represent an abnormality of common pulmonary vein incorporation,[24] this remains controversial. This subject, also, will be discussed later in this chapter.

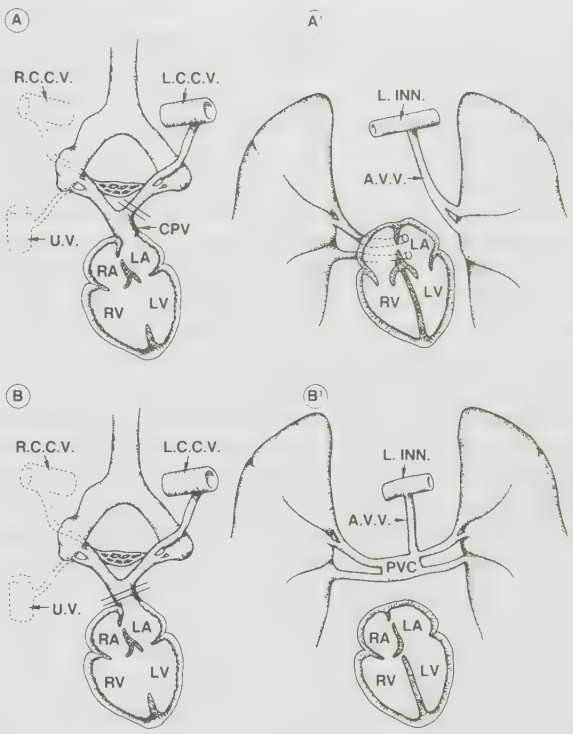

Fig. 69–2. Embryology of anomalous pulmonary venous connections. (A) The primitive left atrium (LA) is connected to the pulmonary venous plexus by the common pulmonary vein (CPV). Partial interruption of this connection early in gestation leads to persistence of ipsilateral systemic venous channels, which results in partial anomalous pulmonary venous connection (A[1]). (B) Complete interruption of the common pulmonary vein results in total anomalous pulmonary venous connection (B[1]). A.V.V., anomalous vertical vein; PVC, pulmonary venous confluence; other abbreviations as in Figure 69–1. PARTIAL ANOMALOUS PULMONARY VENOUS CONNECTION

Partial anomalous pulmonary venous connection (PAPVC) occurs when one or more, but not all, of the pulmonary veins drain into the right atrium directly or indirectly by venous connections. Adachi[25] and Hughes and Rumore[26] have reported PAPVC in 0.7% of autopsy specimens. Healey[7] found 1 case in 251 autopsies and, combining this incidence (0.4%) with those of the previous two studies, determined an overall incidence of 0.6%. The relatively high incidence of this defect observed in autopsy specimens suggests that it is more common than clinical series imply. In fact, many cases of PAPVC do not produce symptoms and are thus not diagnosed during life.

Although PAPVC is associated with other types of cardiopulmonary malformations, there are no known risk factors for the development of this anomaly. In addition, prenatal teratogens (drugs, infections) have not been implicated as causal agents. Risk

of recurrence of the isolated lesion in subsequent siblings of a patient are unknown. Since clinically apparent anomalies in pulmonary venous connection usually occur in patients with associated cardiac defects, the recurrence risks in these families likely parallel those of the associated defect.[27]

Anatomy

Because of the multiplicity of connections between the primitive pulmonary vascular bed and the systemic venous circulation, PAPVC represents a wide spectrum of anatomic variants. Blake et al.[28] observed 27 different variations in 113 selected cases of anomalous venous connection. According to Brody's[2] data, which was confirmed later by Healey[7] and Hickie,[29] the most common types of PAPVC are (in order of decreasing frequency) right pulmonary veins to right superior vena cava, right pulmonary veins to right atrium, right pulmonary veins to inferior vena cava, and left pulmonary veins to the left innominate vein. Connection from the right lung anomalously occurs about twice as frequently as the left. Partial connection to the coronary sinus and azygous vein is less frequent. The more common types of partial anomalous pulmonary venous connection are shown schematically in Figure 69–3A–C.

PAPVC may occur 1) as an isolated defect; 2) in association with other cardiac defects; or 3) in the setting of cardiac malposition and bronchovascular anomalies (scimitar syndrome). PAPVC as an isolated defect is uncommon in patients referred for cardiac evaluation; only 100 cases have been reported as of 1983.[30] The majority of patients who develop signs and symptoms related to this defect usually have two or more anomalously connecting veins; a single anomalous vein is rarely clinically important.

Usually, PAPVC is found in association with other cardiac defects, most commonly an ASD of the secundum or sinus venosus type.[29] Approximately 10% of patients with a proven ASD have PAPVC.[31] Less frequently, partial anomalous pulmonary venous connection has been associated with dextrocardia, azygous continuation of the inferior vena cava, congenital mitral stenosis or atresia, double outlet right ventricle, ventricular septal defect, tetralogy of Fallot, pulmonic stenosis, coarctation of the aorta, patent ductus arteriosus, aortic stenosis, and hypoplasia of the aorta.[31]

PAPVC from the right lung to the inferior vena cava occurs in the Scimitar syndrome. This complex of anomalies, which includes pulmonary hypoplasia or sequestration, diaphragmatic abnormalities, and anomalous systemic arterial supply to the right lung, usually is associated with an intact atrial septum. Associated cardiac defects are seen in approximately one-fourth of patients and include VSD, PDA, coarctation of the aorta, and tetralogy of Fallot. This complex of anomalies represents a more primitive abnormality of development of the right lung buds rather than an isolated abnormality of the primordial pulmonary venous system.[32] A detailed description of the more common anatomic variants follows.

Right Pulmonary Veins to Superior Vena Cava and/or Right Atrium

This abnormality in PAPVC is the most common variant, occurring in 74% of patients studied by Brody.[2] In PAPVC to the superior vena cava (SVC), the right upper and middle lobe veins drain separately into the SVC between the entry of the azygous vein and the right atrial/superior vena caval junction (see Fig. 69–3A). Infrequently, the right upper lobe drains through two or three smaller veins that enter separately into the superior vena cava. The right lower lobe pulmonary vein most often enters the left atrium normally; however, this too may drain anomalously to the right atrium. In the majority of cases, PAPVC to the SVC is associated with an atrial septal defect (ASD) of the sinus venosus type. This defect is located in the superior/posterior portion of the atrial septum near the entrance of the SVC; occasionally, the SVC orifice may override this defect, directing a portion of superior caval flow into the left atrium. Dilatation of the lower SVC occurs in response to increased blood flow through this region.

In most cases of anomalous connection directly to the right

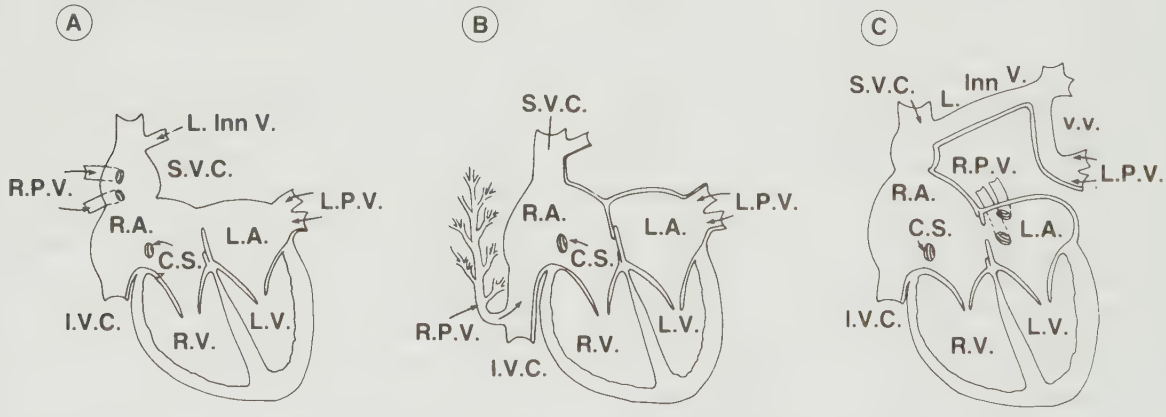

Fig. 69–3. Common types of partial anomalous pulmonary venous connection. (A) Right pulmonary veins (R.P.V.) connecting to superior vena cava (S.V.C.) or high right atrium (R.A.). This anomalous connection is often associated with a sinus venosus atrial septal defect. (B) Anomalous connection from the right lung by a single pulmonary vein to the inferior vena cava (I.V.C.) is usual in the Scimitar syndrome (pulmonary parenchymal abnormalities with anomalous systemic arterial supply). (C) Anomalous connection of one or more left pulmonary veins (L.P.V.) to the left innominate vein (L.Inn.V.) by an ascending vertical vein (V.V.). C.S., coronary sinus; other abbreviations as in Figure 69–2. (Adapted from Lucas, R.V.: Anomalous Venous Connections, Pulmonary and Systemic. *In* Heart Disease in Infants, Children, and Adolescents. Edited by F.H. Adams and G.C. Emmanouilides. 3rd Ed. Baltimore, Williams & Wilkins, 1983.)

atrium, the entire right lung drains anomalously by two or three separate veins. These veins enter at the posterior interatrial groove just to the right of the atrial septum. A sinus venosus type atrial septal defect is most often present, although secundum and primum defects may occur. Rarely, the atrial septum is intact.

Right Pulmonary Veins to Inferior Vena Cava

In this circumstance, most or all of the veins draining the right lung form a confluence and enter the inferior vena cava as a single trunk (see Fig. 69–3B). This trunk forms in the region of the hilum and passes inferiorly and to the left along the greater fissure to enter the inferior vena cava just above or below the diaphragm.[33] Rarely, the trunk may terminate blindly within the diaphragm. Infrequently, only the right middle or right lower lobe pulmonary vein may connect anomalously.

Left Pulmonary Veins to Left Innominate Vein/Coronary Sinus

Anomalous connection from the left lung usually occurs to remnants of the left cardinal system, including the left innominate vein and coronary sinus. Most commonly, the left upper lobe drains to the innominate vein by a single trunk, with the left lower lobe draining normally to the left atrium (see Fig. 69–3C). The nomenclature of the ''anomalous trunk'' that connects the pulmonary veins from the left lung to left innominate vein is debated. Some authors refer to this as a persistent left superior vena cava,[1] which denotes a direct connection to the heart through the coronary sinus. Others refer to it simply as an anomalous vertical vein, which we prefer.[34]

One or more of the left pulmonary veins, usually draining from the left lower lobe, may connect to the coronary sinus. This isolated abnormality is uncommon and was found in only one case in the extensive series of Brody[2] and in no patient in the study of Hickie.[29] Less frequently, anomalous veins from the left lung may drain into the right atrium, inferior vena cava, right superior vena cava, or left subclavian vein. Rarely, anomalous veins from the right lung connect across the midline to the coronary sinus or innominate vein, and one or more veins from the left lung connect to the SVC or right atrium.

Physiology and Hemodynamics

The basic hemodynamic alteration that occurs in PAPVC is a pre-tricuspid left to right shunt, in which fully oxygenated blood is recirculated through the lungs through the right atrium, right ventricle, and pulmonary artery. The increased pulmonary blood flow leads to enlargement of the right atrium, enlargement and hypertrophy of the right ventricle, and dilatation of the pulmonary artery. The left heart chambers are not affected, and systemic cardiac output is normal.

Isolated PAPVC

In the case of PAPVC without associated cardiac defects, the magnitude of the left to right shunt depends on: 1) the number of anomalously draining veins as a percentage of the total pulmonary venous return; 2) the pulmonary segments or lobes from which the anomalous veins originate; and 3) the relative resistances of the normally and abnormally drained pulmonary vascular beds and the compliance of the receiving chambers into which the respective veins empty.[34]

Brody[2] first suggested that hemodynamic abnormalities will not be clinically apparent in patients with isolated PAPVC until 50% or more of the pulmonary blood flow drains anomalously. He based these observations on the finding that 25 of 27 patients (93%) with less than 50% anomalous pulmonary venous connection survived to adulthood, whereas more than half of patients with anomalous pulmonary venous connection draining greater than 50% of the total pulmonary blood flow died in childhood. Hughes[26] studied two patients dying of rheumatic valve disease in middle age, both of whom had PAPVC draining a single lobe. Neither patient had dilatation or hypertrophy of the right heart despite the observation that 25% of total pulmonary blood flow was being shunted left to right. These initial observations have been supported by subsequent studies, suggesting that one lobe connecting anomalously is associated with minimal cardiac pathology and (usually) a normal life span.

The second factor determining the magnitude of left-to-right shunt in PAPVC is the lobe or lobes involved in the anomalous connection. At rest in the upright position, blood flow in the lungs is distributed preferentially to the middle and lower lobes, with minimal flow to the apices of both lungs. Isolated PAPVC from one or the other upper lobes would result in less left-to-right shunt than veins connecting anomalously from the middle to lower lobes. On assuming the supine position or during exercise, pulmonary blood flow is redistributed to the upper lobes, thus increasing the left-to-right shunt. These factors may explain the variation observed in calculated pulmonary to systemic flow ratio in patients undergoing serial hemodynamic evaluation.

The last factor that plays a role in the distribution of pulmonary venous return in PAPVC is regional pulmonary vascular resistance and the downstream compliance to pulmonary venous return. Patients with an abnormal pulmonary vascular bed (such as is seen in some patients with scimitar syndrome) may have elevated pulmonary arteriolar resistance in the lung that drains anomalously. Pulmonary blood flow will proceed preferentially through the normal pulmonary venous pathways through the left lung and tend to reduce the left-to-right shunt. This phenomenon is observed in unilateral pulmonary vein stenosis in which pulmonary arterial flow is shunted to the lung with unobstructed venous return. If the pulmonary arteriolar resistance is equal throughout both lungs, and if the anomalous pulmonary vein connects unobstructed to the right atrium, then pulmonary blood flow will proceed preferentially through this anomalous connection if the right atrial pressure is significantly less than left atrial pressure.[35] When left atrial pressure is elevated abnormally (mitral stenosis), pulmonary blood flow through the anomalous connection will be exaggerated. All of these factors must be taken into account when determining the degree of hemodynamic alteration and, in the final analysis, the indication for surgical intervention in patients with isolated PAPVC.

Although rare, pulmonary hypertension and documented pulmonary vascular disease have been reported in at least 5 patients with isolated PAPVC.[29,35,36] This association most likely represents a coincidental occurrence; a cause and effect relationship is highly unlikely.

PAPVC with Associated Cardiac Defects

PAPVC with an associated small atrial septal defect resembles closely the hemodynamic findings as just described. When the

atrial defect is of considerable size, the additional left-to-right shunt increases the burden on the right heart and pulmonary circulation. Pulmonary blood flow/systemic blood flow ratios of greater than 3:1 are found commonly and result from both a left-to-right shunt through the anomalous venous connection and the left-to-right shunt at the atrial level. A small right-to-left shunt may be detectable by dye curves or contrast echocardiography in certain cases. This usually occurs in the setting of anomalous pulmonary venous connection to the superior vena cava in association with a sinus venosus type atrial septal defect and overriding of the SVC. Systemic arterial desaturation rarely is observed unless intrapulmonary ventilation/perfusion abnormalities are present.

Elevation of calculated pulmonary vascular resistance and pulmonary artery pressure in the presence of PAPVC with only an atrial septal defect has been reported.[29] The incidence probably is similar to that found in an isolated atrial septal defect. Whether the increase in pulmonary blood flow contributed by the additional anomalous pulmonary venous connection leads to earlier pulmonary vascular disease in a susceptible individual is not known.

The physiology in patients with associated intracardiac defects other than ASD most often is determined by the severity of those associated defects. Alpert[35] performed catheterizations on seven patients with PAPVC and mitral stenosis and observed hemodynamic findings consistent with those found in patients with pure mitral stenosis alone. In a number of these patients, pulmonary blood flow to the anomalously draining lung was significantly greater than expected, suggesting that pulmonary venous return followed the path of least resistance and was acting as a compensatory mechanism to decrease the pressure load in the normally connecting pulmonary venous circuit.

Clinical Features

History and Physical Examination

Most patients with PAPVC with or without an interatrial communication do not exhibit symptoms in early life. These patients are often referred with a cardiac murmur or an abnormal chest roentgenogram. When symptoms are elicited at this age, the most common complaint is mild exercise intolerance. Progressive symptoms, if they appear, usually begin in the mid-thirties or early forties. These consist of dyspnea, recurrent bronchitis, hemoptysis, chest pain, and palpitations associated with supraventricular arrhythmias. When overt cardiac failure occurs, its onset is usually rapid.[29] The natural history and clinical findings parallel closely those observed in the symptomatic patient with an ASD.

Respiratory symptoms of dyspnea on exertion and/or recurrent pneumonia may be observed in patients with scimitar syndrome because of pulmonary parenchymal abnormalities. Patients with PAPVC and associated cardiac defects other than an atrial septal defect usually have symptoms and signs related to the associated defect.

Physical examination in patients with isolated PAPVC may be entirely normal if only a single lobe connects anomalously. When multiple lobes are involved, or when there is an associated ASD, the findings are typical of an uncomplicated ASD. There is an increased right ventricular impulse, a basal low-pitched systolic ejection murmur, and wide, fixed splitting of the second heart sound. A diastolic murmur over the tricuspid valve may be detected. Rarely, there may be a low-frequency continuous murmur heard over the base, representing flow through an anomalous venous channel. In older symptomatic patients, cyanosis is found in 50% and is due to both pulmonary hypertension with right-to-left atrial level shunt and also pulmonary venous desaturation.[29] Overt signs of right heart failure (hepatomegaly, jugular venous distention, ascites) may be observed in the older, severely affected patient.

Electrocardiogram

The electrocardiogram most often reveals right ventricular hypertrophy of the volume type with a rR′ pattern or a rSR′ pattern in the right precordial leads. In the older patient with pulmonary hypertension, right atrial enlargement and severe right ventricular hypertrophy are seen. The electrocardiogram may be normal in patients without associated cardiac defects.

Atrial arrhythmias, including atrial flutter and fibrillation, may occur in the third and fourth decade and usually are associated with an atrial septal defect or mitral stenosis. The development of these arrhythmias relates to the magnitude of left-to-right shunt and subsequent atrial dilatation, although some studies have suggested a correlation with the onset of pulmonary hypertension.[37] Kyger[38] found atrial arrhythmias in 14% of patients undergoing operation for sinus venosus atrial septal defect and PAPVC. The mean age of operation in these patients was 14 years. The incidence of atrial arrhythmias increases with age and was found in 55% of patients older than 60 years undergoing surgery for an isolated ASD or an ASD associated with PAPVC.[39]

Radiographic Features

The chest roentgenogram often shows, in the presence of an atrial septal defect, evidence of right atrial and right ventricular enlargement in addition to increased pulmonary vascularity. In the absence of an atrial defect or other associated anomalies, the chest roentgenogram is usually normal.

Specific findings related to the insertion or drainage of the anomalous pulmonary venous connection have been well described. When veins from the left lung enter a confluence and drain to the left innominate vein, the abnormal vessel may be seen as a widened superior mediastinum on the left. This structure may be seen to pulsate under fluoroscopy. Increased blood flow in the left innominate vein and superior vena cava may cause enlargement of these structures, thus forming the classic figure-eight pattern first reported by Snellen and Albers.[40] In cases in which anomalous right pulmonary veins enter the superior vena cava, a widened superior vena cava/right atrial segment and a prominent vascular structure extending into the right upper lobe may be visible.

The most widely described radiographic finding in PAPVC occurs when the right lung drains anomalously by a single trunk to the inferior vena cava at the level of the diaphragm, the anomalous trunk resembling a curved scimitar sword. This classic finding, when associated with malposition of the heart and hypoplasia of the right lung with aberrant systemic arterial supply, was termed scimitar syndrome by Neill[32] in 1960 (Fig. 69–4).

Echocardiography

PAPVC with or without an atrial septal defect has M-mode echocardiographic findings similar to those reported for atrial septal defects alone.[41] There is mild to moderate dilatation of the right ventricle and usually paradoxical interventricular septal motion.

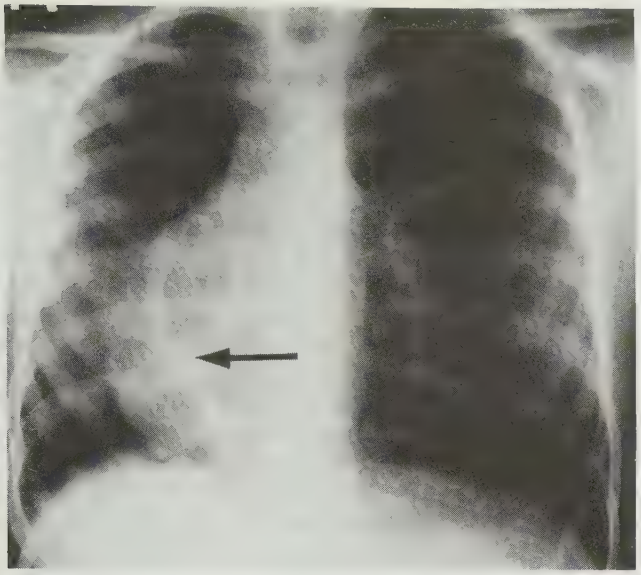

Fig. 69–4. Scimitar syndrome. Chest radiograph in a patient with dextrocardia and partial anomalous pulmonary venous connection from the right lung to the inferior vena cava. Arrow points to the anomalous (Scimitar) vein. (Courtesy of Teresa Stacy, M.D.)

High-resolution two-dimensional ultrasound imaging of intracardiac structures and intrathoracic arteries and veins has supplanted M-mode echocardiography as the prime noninvasive diagnostic procedure of choice in patients with suspected abnormalities of pulmonary venous connection. The addition of pulsed and continuous-wave Doppler echocardiography has expanded the ability to assess abnormalities in structure as well as function in these patients.

In infants and young children, the interatrial septum can usually be well visualized using two-dimensional imaging from the subcostal four-chamber view. Atrial defects of the sinus venosus type, which occur more commonly with PAPVC, may be difficult to image in this routine tomographic plane.[42] Visualization of this defect may be enhanced by clockwise rotation of the imaging plane from the subcostal four-chamber view 90 degrees to a subcostal sagittal plane. Using this technique, the posterior/superior atrial septum is interrogated easily. If a defect of the sinus venosus type is detected, then a diligent search for anomalous pulmonary venous connection should be performed.

Direct visualization of anomalous pulmonary venous connections requires a knowledge of anatomy as well as a high index of suspicion. When the clinical diagnosis of PAPVC is suspected or in the presence of a sinus venosus ASD, careful scanning in the suprasternal and subcostal planes should be performed to detect the absence of one or more normally connecting pulmonary veins. If all four veins are not visualized, imaging the left innominate vein to its birfurcation should be performed. Partial anomalous pulmonary venous connection from the left lung may be visualized as a vascular structure entering the inferior aspect of the left innominate vein. Doppler interrogation of this structure will reveal a venous flow pattern in a cranial direction and thus establish the diagnosis. Although somewhat more difficult to observe, the anomalous right pulmonary vein connecting to the superior vena cava also should be apparent from the suprasternal notch with scanning in the suprasternal short axis or sagittal plane. Subcostal short and long axis scans at the level of the inferior vena cava/right atrial junction should be performed in all patients in whom the diagnosis of Scimitar syndrome is being considered. Finally, scanning of the posterior left atrioventricular groove will reveal an enlarged coronary sinus in patients with partial anomalous connection to this location. Using a step-by-step sequential approach, the more common types of PAPVC will be readily detected or at least highly suspected. One must remember, however, that structures coursing outside the mediastinum in the lung parenchyma cannot be visualized due to acoustic interference from air-filled lung. Because of these limiting factors, many patients will require further diagnostic studies in order to delineate precisely the complete anatomy of the suspected lesion.

Cardiac Catheterization and Angiography

Cardiac catheterization with selective angiography remains the definitive diagnostic procedure in most patients with suspected PAPVC with or without associated cardiac defects. Dotter and associates[13] in 1949 first reported the catheterization and angiographic findings in 2 patients with PAPVC to the inferior vena cava. The first large series was by Friedlich[14] in which he reported findings on 16 patients with PAPVC. Refinements in catheterization technique and the introduction of axial cineangiography further enhanced the ability to define both anatomic and hemodynamic alterations in this lesion.

From the femoral vein approach, the anomalous vein may be entered directly during catheter probing. If the catheter passes directly into a pulmonary vein from the right lateral border of the right atrium or low superior vena cava, the diagnosis of anomalous pulmonary venous connection from the right lung to this region should be suspected. The catheter course in this circumstance may be confused with a normal course in which the catheter crosses a patent foramen ovale or an ASD and enters the normally connecting right upper pulmonary vein. One may resolve this question by 1) observing an initial posterior course of the catheter in the left anterior oblique view or 2) slow withdrawal from the vein observing a quick rightward slip of the catheter tip some distance from the right atrial border.[31]

Manipulation of the catheter into the left innominate vein should always be performed in suspected cases with oximetry sampling distally and at the innominate vein/SVC junction. Probing in the left innominate vein at the mediastinal border is done to detect an anomalously connecting pulmonary vein from the left lung. Oximetry sampling should be performed at multiple sites during a pull back from the high superior vena cava into the body of the right atrium to discern a significant step up (7 to 10%) in oxygen saturation. Although an isolated sinus venosus type atrial septal defect may imply an anomalous pulmonary venous connection at the SVC/right atrial junction, selective axial cineangiography should resolve this question. In cases of suspected Scimitar syndrome, the inferior vena cava should be investigated thoroughly. Oximetry sampling may be confusing in this region because of the higher oxygen saturations that normally occur in the IVC due to the high renal vein oxygen content.

Intracardiac pressures are most often normal in patients with PAPVC when less than 50% of the pulmonary veins connect anomalously. The exceptions to this include patients older than 40 years of age with an associated ASD,[29,38,39] those with concomitant

mitral stenosis,[43] and those with the scimitar syndrome.[33,44] In these circumstances, elevation of right atrial, right ventricular, and pulmonary artery pressures may be observed.

Cineangiography

Selective cineangiography should be performed in all cases of suspected PAPVC in patients undergoing cardiac catheterization. The levophase of a selective right or left pulmonary artery angiogram may reveal the lobe or lobes that are connected anomalously. Further delineation by lobar or segmental injection may be required. If the anomalous vein can be entered directly, injection of contrast material into the anomalous connection with angulated cineangiography is helpful to define both the connection and drainage in cases of PAPVC (Fig. 69–5).

Indicator dilution studies[45] and contrast echocardiography[46] may be useful adjuncts during catheterization to delineate some forms of PAPVC. We have not used these methods extensively but think they may have a place in certain diagnostic situations.

Other Diagnostic Modalities

Newer imaging modalities have been developed recently that may have application in both anatomic diagnosis or hemodynamic assessment of these cardiac defects. These include radionuclide angiocardiography and magnetic resonance imaging (MRI).

The application of radionuclide studies in congenital heart disease has been discussed recently in depth by Hurwitz and Treves.[47] First-pass angiocardiography provides an anatomic delineation of intracardiac and extracardiac vascular structures and also can be used to quantitate shunting between the pulmonary and systemic circulations. The anatomic detail provided by radionuclide studies is inferior to those of high-resolution echocardiography and selective angiography, however, and should be used in conjunction with these modalities in the preoperative assessment. Serial studies using first-pass radionuclide angiocardiography to predict pulmonary to systemic blood flow ratios (Qp/Qs) would appear helpful in following patients who are borderline surgical candidates.

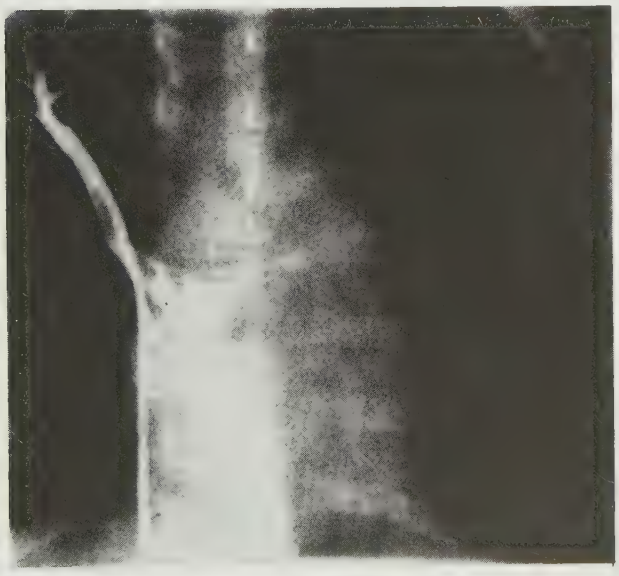

Fig. 69–5. Angiography in PAPVC. Direct contrast injection into the right upper pulmonary vein demonstrates anomalous connection to the high right atrium.

Cardiac-gated magnetic resonance imaging (MRI) is a noninvasive technique that demonstrates in fine detail both intracardiac and intrathoracic anatomy without the use of ionizing radiation. The utility of this methodology to supplant more conventional imaging techniques, however, is yet to be demonstrated. Further studies using MRI are forthcoming, and will likely complement the well-established diagnostic techniques.

Natural History of PAPVC

In patients with isolated PAPVC without associated defects, the prognosis depends on the number of pulmonary veins draining anomalously. Studies based on autopsy material[2,26] indicate that patients with a single pulmonary vein connected anomalously and an intact atrial septum rarely have symptoms and have a normal life expectancy. Patients in whom more than 50% of pulmonary veins drain anomalously or who have an associated ASD have a natural history and prognosis similar to that of an ASD alone. When symptoms develop, they do so in the third or fourth decade and are due to either right heart failure, pulmonary hypertension with cor pulmonale, or atrial arrhythmias.

Atrial arrhythmias may precipitate cardiac decompensation in patients with simple or complex PAPVC. The development of arrhythmias has been associated with both the size of the left-to-right shunt and the presence of pulmonary hypertension.[29] The incidence of arrhythmias increases with age in symptomatic patients and was found in 55% of patients older than 60 years undergoing operative correction for ASD with or without PAPVC.[39]

In the absence of an intracardiac communication, isolated PAPVC does not carry a risk of paradoxical systemic embolization. The absence of this risk factor must be considered in decisions regarding the need for operative intervention in patients with borderline hemodynamic criteria.

Medical Therapy

In asymptomatic patients who are not surgical candidates, no specific medical therapy is warranted. In older patients who develop symptoms of congestive heart failure, cor pulmonale, or arrhythmias, symptomatic relief can be obtained with the use of a diuretic, inotropic agent, and specific antiarrhythmic therapy.

Surgical Treatment

Surgical treatment of PAPVC should be considered in the following circumstances: 1) In the presence of a hemodynamically significant left-to-right shunt (Qp:Qs greater than 2:1, cardiomegaly on chest radiograph). This will include most patients with isolated PAPVC in which 50% or more of the pulmonary veins connect anomalously; 2) in patients with recurrent pulmonary infections in association with the Scimitar syndrome; 3) in conjunction with surgical repair of other major cardiac lesions (ASD, mitral stenosis); 4) when the anomalous connection affects surrounding structures by compression or obstruction. Although not previously reported in PAPVC, obstruction of the left main stem bronchus by an anomalous left vertical vein resulting in severe unilateral emphysema has been reported in total anomalous pulmonary venous connection.[48] In asymptomatic patients with PAPVC from a single lobe who do not fall into one of the above categories, surgical intervention is rarely indicated.

Although cardiac catheterization often is performed prior to operative correction, some patients may be candidates for surgical repair based on one or more noninvasive studies alone (echocardiography, radionuclide angiography). In patients with the typical clinical and echocardiographic findings of an atrial septal defect, Freed et al.[49] found no difference in operative morbidity or mortality in patients who did and in those who did not have preoperative cardiac catheterization. In that study, the diagnostic accuracy of noninvasive assessment compared favorably with invasive catheterization and angiography (85% vs. 90%). In the patients who had additional PAPVC undiagnosed prior to operation, all were discovered quickly at the time of surgery and repaired without major intraoperative problems.

The surgical technique for PAPVC varies and should be tailored to the anatomy involved and the associated intracardiac defects. The approach is usually through a midline sternotomy except in cases of anomalous venous connection to the inferior vena cava, in which case an extended thoracotomy is required. PAPVC to the right atrium usually is corrected in association with closure of an atrial septal defect. A patch of synthetic woven Dacron or pericardium is used to direct the anomalous veins through the right atrium to the atrial defect. At times, the atrial defect must be enlarged to facilitate this procedure.

When anomalous pulmonary venous connection to the superior vena cava is found, different surgical procedures have been recommended[50–53] because of the variable location and number of veins connected to the superior vena cava, the proximity of the sinus node to the area under consideration, and the propensity for development of pulmonary and systemic venous obstruction after this repair. Two major approaches include: 1) partitioning of the superior vena cava and approximation of the left lateral and caudal margins of the septal defect to the right atrial wall by direct sutures; 2) diversion of the anomalous flow by suturing a patch of pericardium or synthetic material around the opening of the anomalous veins and the margin of the septal defect.[54] To ensure unobstructed SVC flow, a free pericardial graft often is used as a gusset to enlarge the SVC/right atrial junction (Fig. 69–6). The right atrial appendage has been used as a flap to enlarge this area.

PAPVC to the inferior vena cava often is associated with anomalies of systemic arterial supply from below the diaphragm and pulmonary parenchymal abnormalities (sequestration). It is critical that the pulmonary arterial supply and pulmonary venous return be defined accurately prior to operative repair. Numerous reports of complete ligation of the entire venous return from the right lung during partial pneumonectomy for a sequestered lobe (many with lethal consequences) have been reported. In the usual circumstance, the common pulmonary vein is transected and reattached to the right atrial wall. An ASD is used or one is created; this vein is then connected to the left atrium by an intracardiac baffle using pericardium or synthetic material.

In most cases of PAPVC to the left innominate vein, the common trunk is mobilized and anastomosed directly to the left atrium or left atrial appendage. If this is done without extracorporeal circulation, the appropriate pulmonary artery must be occluded to prevent the development of severe pulmonary edema in the ipsilateral lung.

Outcome

Operative mortality in asymptomatic patients with PAPVC with or without an atrial septal defect is low and should parallel that of an ASD alone. Kyger et al.[38] reported no deaths in 109 patients operated on for sinus venosus ASD and PAPVC. Two other centers have reported no operative deaths in this lesion as well.[55,56]

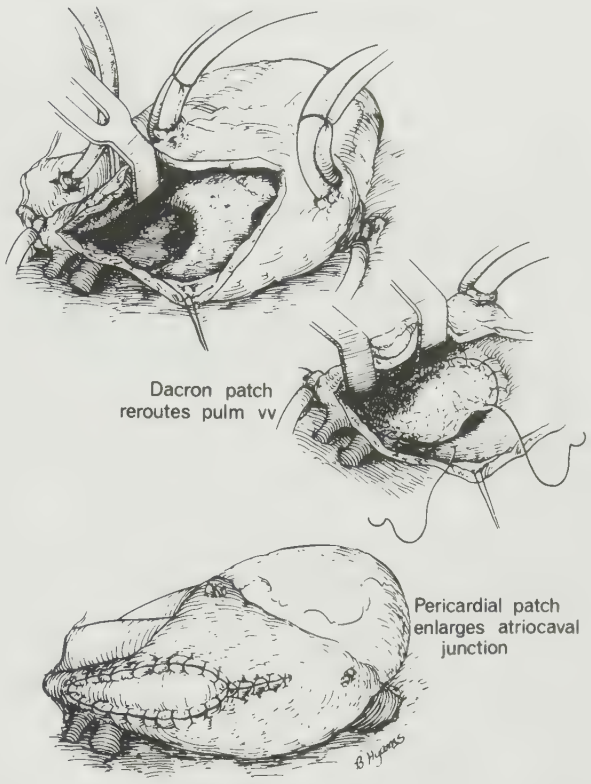

Fig. 69–6. Surgical repair of PAPVC associated with sinus venosus atrial septal defect. (Top) Atrial septal defect is visualized through the open right atrium. (Middle) Dacron patch closes the ASD and directs the two anomalous pulmonary veins to the left atrium. (Bottom) Pericardial patch is used to close the right atrium to avoid obstruction to the superior vena cava. (Reprinted with permission from Kyger, E.R., et al.: Sinus venosus atrial septal defect: Early and late results following closure in 109 patients. Ann. Thorac. Surg., 25:45, 1978.)

In older patients who have developed symptoms or who have elevated pulmonary vascular resistance, the operative risk is slightly increased. In a series of 66 patients older than 60 years undergoing operation for an ASD with or without PAPVC, the operative mortality was 6%.[39] In addition, an improvement in functional status was observed in 87% of survivors, including four of five with calculated pulmonary arterial resistance greater than eight units.

Late complications following surgery are rare. Obstruction to systemic or pulmonary venous return has been reported, usually in association with repair of PAPVC to the superior vena cava. Atrial tachy- and bradyarrhythmias also have been observed.

In summary, accurate diagnostic studies to include both precise delineation of the pulmonary venous anatomy and a functional assessment of the myocardium are required in patients with PAPVC in order to make reasonable and knowledgeable decisions concerning surgical intervention. In well-selected surgical patients, a good functional result can be realized and a normal or near-normal longterm outcome can be expected.

TOTAL ANOMALOUS PULMONARY VENOUS CONNECTION

Total anomalous pulmonary venous connection (TAPVC) occurs when all pulmonary veins from both lungs drain into the right atrium or into a venous channel in communication with the right atrium. In all cases of TAPVC, systemic blood flow is maintained by way of right to left shunting through an atrial septal defect or, more commonly, a patent foramen ovale. In the group of patients with this abnormality, approximately one-third have other significant major cardiac malformations including single ventricle, atrioventricular canal defect, hypoplastic left heart, patent ductus arteriosus, and transposition of the great vessels.[57] Many patients in this group have been found to have abnormalities of atrial and visceral situs associated with the heterotaxy syndrome (asplenia and polysplenia). In two-thirds of cases, TAPVC occurs as an isolated abnormality associated with only an interatrial communication.

The incidence of TAPVC in autopsy series of patients dying of congenital heart disease varies from less than 1% in the study by Maude Abbott[58] to as high as 5%.[12] The incidence of TAPVC in the New England Regional Infant Cardiac Program[59] was 2.6%. The male to female sex ratio is equal in most cases of TAPVC; however, there is a strong male predominance (three to one) in infants with TAPVC of the infradiaphragmatic type.[60,61]

Genetics and Epidemiology

Because of the relatively low incidence of TAPVC in the spectrum of congenital heart disease, studies on genetic transmission of this defect are scarce. Paz and Castilla[62] reported three patients with TAPVC in one family. Results of chromosome studies of the three patients and the parents were normal. The authors speculated that the mechanism of transmission was either an undetectable small chromosome translocation or a single autosomal-dominant gene mutation with complete nonpenetrance in the parents. Most cases of TAPVC are sporadic and are likely due to a multifactorial inheritance pattern as described by Nora.[27] Although TAPVC often is associated with abnormalities of the asplenia and polysplenia syndromes, it is rare in other syndromes or in patients with chromosomal abnormalities.[63] TAPVC has not been associated with environmental teratogens nor is it associated with premature birth.[59]

Anatomy of TAPVC

A number of classification systems have been proposed to describe the different types of TAPVC, including one based on embryologic considerations according to Neill[11] and another based on the length of the anomalous channel and the size of the interatrial communication.[64] We will use the system described by Darling, Rothney, and Craig[12] to categorize TAPVC according to the anatomic location of the anomalous connection. Based on this system, the anatomic variations and the frequency with which they occur are as follows:

Type 1: anomalous connection at the supracardiac level (55%)
Type 2: anomalous connection at the cardiac level (30%)
Type 3: anomalous connection at the infracardiac level (13%)
Type 4: anomalous connection at two or more levels (2%)

From a functional standpoint, we will use the term *obstructed TAPVC* to denote impedance to pulmonary venous return occurring between the common pulmonary venous confluence and the right atrium. We will use the term *restrictive interatrial communication* to denote obstruction to blood flow from the right atrium to the left atrium and, hence, the systemic circulation. This distinction is important in understanding the altered hemodynamics observed and variations in clinical symptoms that occur in patients with this cardiac defect.

Supracardiac Type (Type 1)

This lesion is responsible for the majority of cases of TAPVC in most clinical and autopsy series. Connection to the left innominate vein is most common, accounting for 44% of all cases of TAPVC in the series by Darling.[12] In connections of this type, two pulmonary veins from each lung converge directly behind the left atrium and form a common pulmonary venous confluence. An anomalous vertical vein then arises from the left portion of the confluence and usually passes anterior to the left pulmonary artery and left mainstem bronchus on its course to the left innominate vein (Fig. 69–7A). The left innominate vein then empties normally into the right superior vena cava. Obstruction to pulmonary venous return is relatively uncommon in this lesion; when it occurs, it is due to either intrinsic narrowing or extrinsic compression of the anomalous vertical vein. Intrinsic narrowing occurs either at the origin of the ascending vein or at the insertion of this vein in the innominate vein. Extrinsic compression is found in cases in which the anomalous vertical vein courses between the left pulmonary artery anteriorly and the left mainstem bronchus posteriorly.

Anomalous connection to the right superior vena cava occurs much less frequently and often is associated with complex cardiac malformations.[65] The anomalous venous trunk arises from the right side of the confluence, ascends anteriorly to the hilus of the right lung and enters the posteromedial aspect of the superior vena cava. The entrance to the SVC usually is separate from the azygous vein, although instances of anomalous connection to the azygous vein have been reported. Obstruction may occur by extrinsic compression of the anomalous ascending vein between the right pulmonary artery and the trachea or may occur where the ascending vein enters the superior vena cava.

Cardiac Type (Type 2)

Under these circumstances, the pulmonary veins connect at the level of the coronary sinus or in the posterior-right atrium near the midatrial septum. The anomalous veins may connect by a short common channel or may connect by three or four separate openings (Fig. 69–7B,B′). In TAPVC to the coronary sinus, the coronary sinus ostium is enlarged dramatically but normally placed between the entrance of the inferior vena cava and tricuspid valve (Fig. 69–7C). The great cardiac vein drains into this enlarged ostium of the coronary sinus and hence to the right atrium.

Many authors have considered obstruction to pulmonary venous return[66,67] to be rare in patients with direct cardiac connections. Recent data suggest, however, that obstruction to pulmonary venous return may be more common than previously appreciated in this anatomic subgroup. Jonas and colleagues[68] found obstruction in 22% of unoperated and operated patients with TAPVC to the coronary sinus. They observed that obstruction occurred when a very short, narrow segment of a common vertical vein connected the horizontal right and left pulmonary veins to the ostium of the

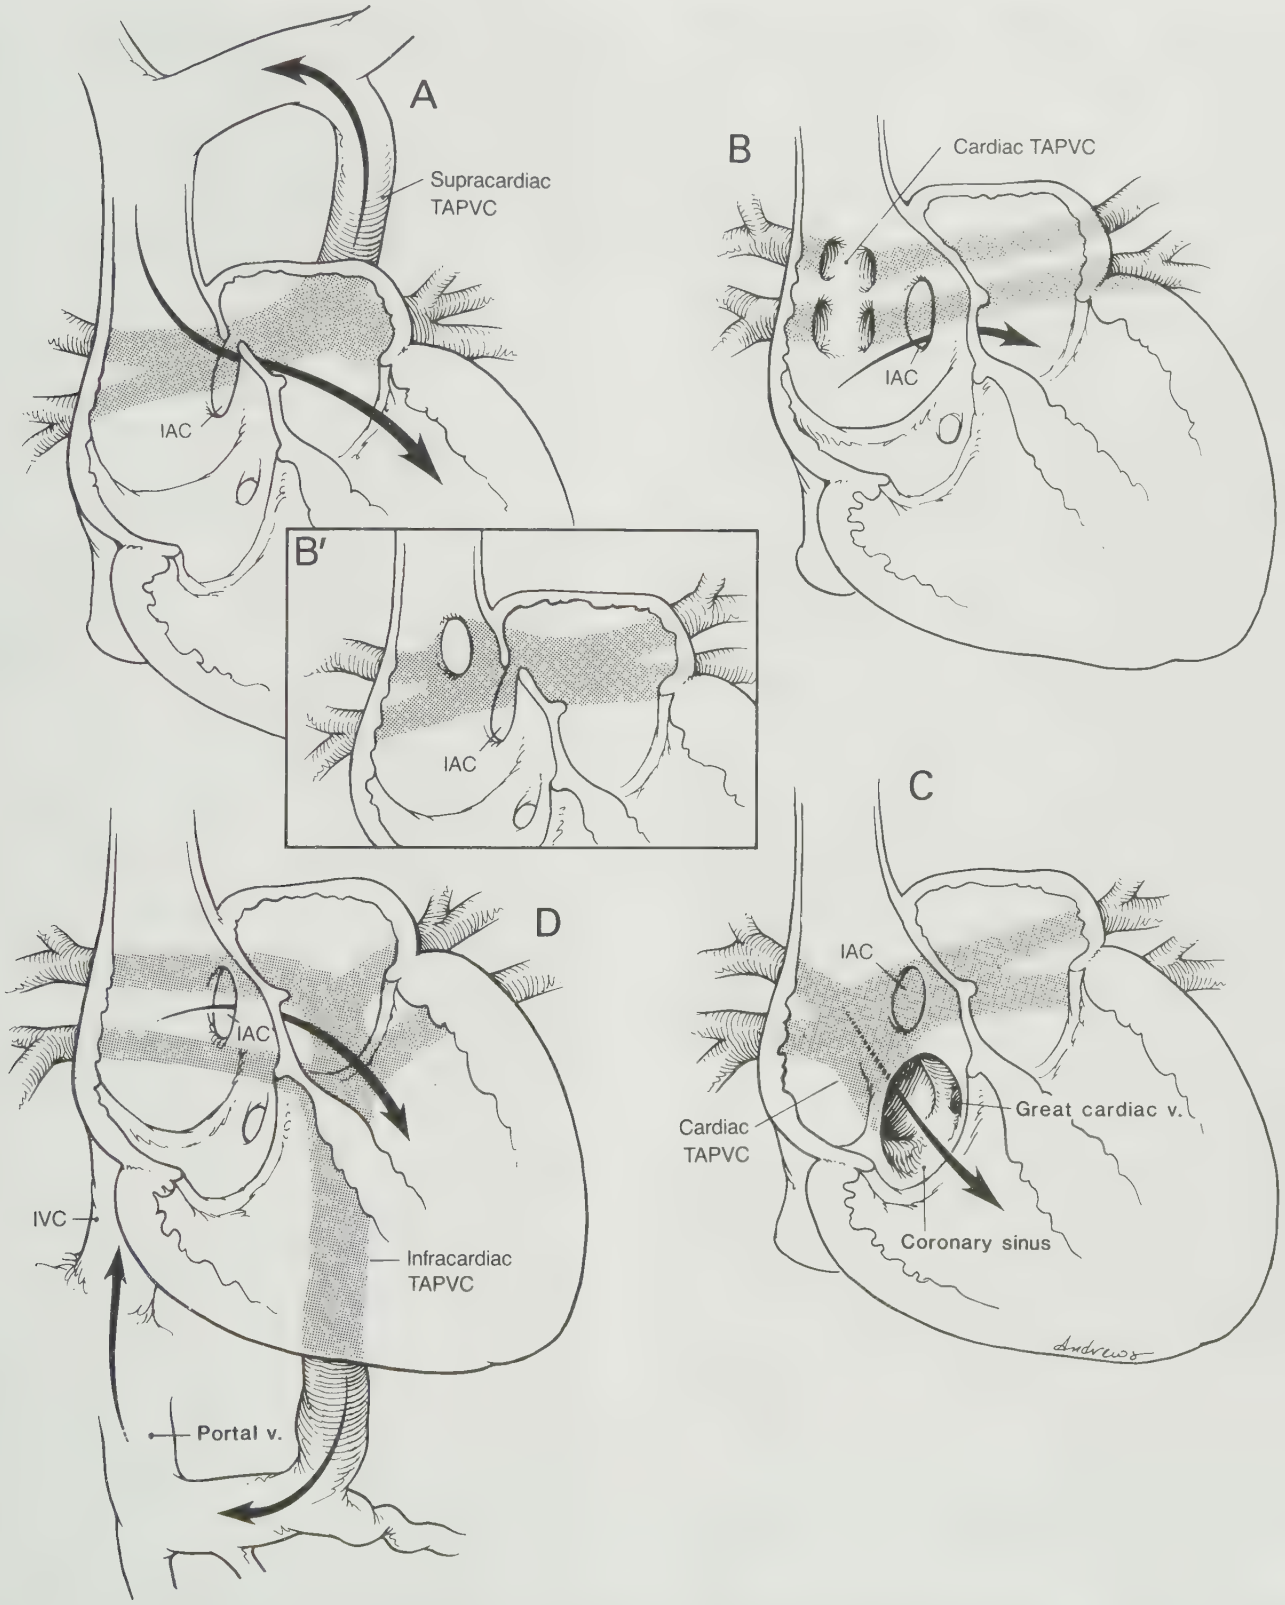

Fig. 69–7. Types of total anomalous pulmonary venous connection. (A) Supracardiac connection to left innominate vein. (B) Cardiac connection via four separate veins. (B[1]) Cardiac connection by single common orifice. (C) Cardiac connection to coronary sinus. (D) Infracardiac (subdiaphragmatic) connection to portal system. (Adapted from Reardon, M.J., et al.: Total anomalous pulmonary venous return: Report of 201 patients treated surgically. Texas Heart Inst. J., *12*:131, 1985.)

coronary sinus. Obstruction also has been reported in the individual pulmonary veins on entering the common venous channel due to intimal proliferation,[69] a finding not unlike that observed in isolated pulmonary vein stenosis.

Infracardiac Type (Type 3)

Anomalous pulmonary venous connection of this type also has been referred to as infradiaphragmatic TAPVC. This type of connection almost always is associated with a severe degree of obstruction to pulmonary venous return and most often causes symptoms very early in the newborn period. Usually, the pulmonary veins from both lungs converge to a confluence directly behind the left atrium. From this confluence, a descending vein courses anterior to the esophagus and traverses the diaphragm through the esophageal hiatus (Fig. 69–7D). In the majority of patients (70 to 80%),[12,61] this anomalous descending vein then joins the portal venous system, either at the splenic vein or at the confluence of the splenic and superior mesenteric veins. The descending vein may, on occasion, connect directly to the ductus venosus. Rarely, the connection is to one of the hepatic veins or to the inferior vena cava.[61] There are, however, variations of this pattern. The most common is a long vertically oriented common pulmonary venous chamber with insertion of the pulmonary veins from the lower segments of each lung occurring near the esophageal hiatus some distance from the upper lobe pulmonary veins.

Obstruction to pulmonary venous return may occur at a number of sites along the anomalous venous pathway. *Discrete obstruction* due to intrinsic narrowing or extrinsic compression may occur 1) at the level of the esophageal hiatus, 2) at the junction of the descending vein/portal vein connection, or 3) at the ductus venosus after constriction or closure of this vessel. In addition, *diffuse obstruction* occurs when pulmonary venous blood entering the portal circulation must traverse the hepatic sinusoids. Thus, the length of the anomalous venous channel and the large number of possible sites for pulmonary venous obstruction predicts that most patients with infracardiac TAPVC will manifest symptoms very early in the newborn period.

Mixed Type (Type 4)

This variation of total anomalous pulmonary venous connection occurs in fewer than 5% of reported series.[12] The most common pattern of mixed TAPVC involves drainage of the left lung through a vertical vein to the left innominate vein, and the right lung connected either to the right atrium or coronary sinus. Rarely, the veins from the right lung will connect infradiaphragmatically to the portal vein. Mixed TAPVC is associated more commonly with other major cardiac anomalies.[2] As described previously, obstruction at one or more veins can occur in this type of anomaly; the type and location depend on the site of anomalous connection.

Associated Cardiac Anomalies

Total anomalous pulmonary venous connection with significant other cardiac anomalies occurs in approximately one-third of patients. These associated defects include single ventricle, truncus arteriosus, transposition of the great arteries, pulmonary atresia, coarctation of the aorta, and anomalies of systemic venous return.[34] The hemodynamic abnormalities observed in patients with complex TAPVC are related both to the TAPVC itself (with or without obstruction) and to the predominant associated cardiac defect. Hemodynamic interactions between defects may occur and, at times, lead to confusing clinical signs and symptoms. An example of this is occult pulmonary venous obstruction in patients with TAPVC and marked decrease in pulmonary blood flow (severe pulmonary stenosis or atresia). Under these circumstances, pulmonary venous obstruction may be subclinical until pulmonary blood flow is augmented by medical or surgical therapy.

Total anomalous pulmonary venous connection occurs commonly in patients with abnormalities in atrial and visceral situs (asplenia and polysplenia syndromes). Asplenia, or right isomerism, is associated with the presence of two atrial chambers, both of which have right atrial morphology. This developmental complex usually is accompanied by a complete atrioventricular canal defect, single ventricle, pulmonary stenosis or atresia, and malposition of the great vessels. Because this type of heart lacks a morphologic "left atrium," TAPVC occurs in all of these patients. The pulmonary venous connection pattern commonly found in patients with right isomerism is depicted in Figure 69–8. The pulmonary veins connect to a pulmonary venous confluence, which then drains to either the right or left superior vena cavae or directly to the morphologic right atria through a single orifice.[70] Common associated noncardiac malformations include bilateral morphologic right lungs, abdominal visceral heterotaxia, and malrotation abnormalities of the gastrointestinal tract.

In contrast, patients with the polysplenia syndrome (left isomerism) have bilateral morphologic left atria and, in most circumstances, less severe associated cardiac defects. Pulmonary venous connection may occur to either the right- or left-sided atrium. In most cases, however, the right pulmonary veins connect to the right-sided atrium and the left veins to the left-sided atrium. Although some embryologists would argue that TAPVC does not exist in polysplenia (all pulmonary veins connect to a morphologic left atrium), we prefer to consider this an abnormality of pulmonary venous connection because of the obvious surgical implications.

Asplenia and polysplenia syndromes will be discussed in depth in Chapter 75. The next discussion focuses primarily on TAPVC

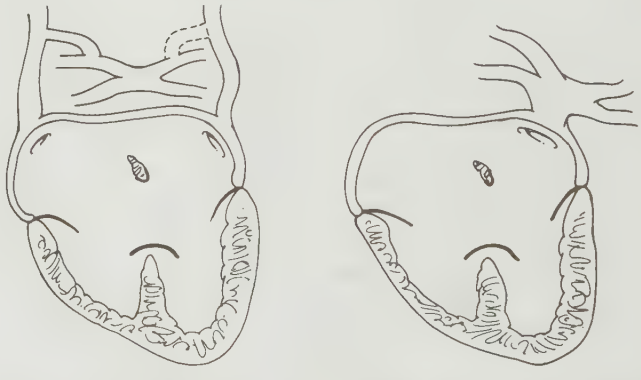

Fig. 69–8. Pulmonary venous connection pattern found in patients with right atrial isomerism. The pulmonary veins connect to a pulmonary venous confluence, which then drains to either of the superior cavae (left) or to either of the morphologic right atria (right). (Reprinted with permission from Huhta, J.C.: Pediatric Imaging/ Doppler Ultrasound of the Chest. Philadelphia, Lea & Febiger, 1986, p. 150, Figure 10–4.)

as an isolated abnormality (with only the obligatory atrial septal defect) not associated with complex cardiac disease.

Pathophysiology

The primary physiologic derangement in patients with TAPVC is mixing of both pulmonary venous and systemic venous blood in the right atrium. From the right atrium, this mixed venous blood is distributed either to the systemic circulation by an obligatory interatrial communication, or to the pulmonary circulation by the right ventricle and pulmonary artery. The factors that determine blood flow distribution in these two circuits and, thus, the predominant clinical symptoms include 1) the presence and severity of obstruction in the extracardiac pulmonary venous channels and 2) the relative size of the interatrial communication. Although these two factors are not mutually exclusive in a given patient, one usually is predominant and determines the clinical course. Therefore, we will discuss each separately.

TAPVC with Obstruction in the Pulmonary Venous Channels

Obstruction in the pulmonary venous channels usually is due to *discrete intrinsic narrowing* of the vessel itself or to *extrinsic compression* by surrounding structures. In addition, some authors think the length of the anomalous venous channel affects blood flow in the pulmonary venous system, with longer channels resulting in greater degrees of impedance to pulmonary venous return.[64] Another source of obstruction in patients with infradiaphragmatic TAPVC occurs when the descending anomalous vein drains into the portal venous system and must traverse the hepatic sinusoids.

In all cases of obstruction to pulmonary venous return, pulmonary venous pressures become elevated. This elevation of pressure is transmitted to the capillary bed and results in progressive interstitial and alveolar edema. Compensatory mechanisms are invoked to minimize this increased lung water and include increase in pulmonary lymph flow, recruitment of alternate pulmonary venous–bronchial venous anastomoses, and reflex pulmonary vasoconstriction.[34] With this marked increase in pulmonary resistance, the right ventricular systolic and end-diastolic pressures increase; the right ventricular compliance decreases; impedance to right ventricular filling occurs; and pulmonary blood flow diminishes. Elevation in right atrial pressure leads to an increase in right-to-left shunt across the interatrial communication and progressive systemic hypoxemia. The right-to-left shunt allows decompression of the right atrium and right ventricle; for this reason the heart is not usually enlarged on chest radiograph. If the ductus arteriosus remains patent, predominant right-to-left shunting occurs, thereby increasing pulmonary oligemia. Progressive systemic hypoxemia leads to metabolic acidemia and multisystem organ failure. Without relief of the obstruction in the anomalous venous channel, death ensues. The size of the interatrial communication (whether a patent foramen ovale or an atrial septal defect) probably does not influence the outcome in these patients.

Because of prominent right-to-left shunting at both the atrial and ductal level and the ensuing severe hypoxemia, TAPVC with obstruction often is confused with persistent fetal circulation if the pulmonary veins are not delineated thoroughly during echocardiographic examination.

TAPVC with a Restrictive Interatrial Communication

Some type of interatrial communication (IAC) is needed to maintain systemic blood flow in patients with TAPVC. The size of this communication plays a critical role in the distribution of mixed venous blood between the pulmonary and systemic circulations in the absence of significant obstruction in the pulmonary venous channels. A patent foramen ovale is found in 70 to 80% of infants with uncomplicated TAPVC[12,64,71] and imposes some degree of restriction to left atrial and left ventricular filling in the majority of infants.[71] The remaining patients have a nonrestrictive IAC, usually an atrial septal defect of the secundum type. The postnatal hemodynamics and clinical course are different, depending on whether the IAC is restrictive.

Blood flow across the foramen ovale in the fetus with TAPVC is only mildly increased due to the normally high pulmonary vascular resistance and the relatively small amount of pulmonary venous blood returning anomalously to the right atrium. The stimulus for development of a large IAC, as would be present in patients with right heart obstructive lesions (tricuspid atresia, pulmonary atresia with intact ventricular septum), therefore does not occur. Soon after birth, systemic cardiac output is maintained across this adequate IAC. However, as pulmonary vascular resistance diminishes and pulmonary blood flow increases, right ventricular filling is enhanced. Blood returning to the right atrium is shunted preferentially away from the high-resistance foramen ovale. With rapid growth in the first few weeks and months of life, demands for systemic output increase and cannot be met because of the non-restrictive interatrial communication. Massive pulmonary overcirculation in the face of a fixed systemic cardiac output leads to progressive cardiopulmonary dysfunction. We have observed that symptomatic congestive heart failure does not occur in the first few days and weeks of life in infants with nonobstructed TAPVC and a restrictive IAC, but develops in the second month of life and can be partially or totally relieved by transvenous atrial septostomy.[71]

Elevation of right atrial pressure occurs in response to the restrictive IAC and leads to both systemic and pulmonary venous congestion. Pulmonary blood flow ranges from 1.5 to 5 times systemic flow and results in marked right ventricular dilatation and displacement of the interventricular septum into the left ventricular cavity. Pulmonary arterial pressure was greater than one-half systemic pressure in all patients in our study.[71] The elevation of pulmonary arterial pressure in infants with a restrictive IAC usually is due to torrential pulmonary blood flow rather than elevation of pulmonary vascular resistance. Histologically, the muscular pulmonary arteries and arterioles have only medial hypertrophy. Mild proliferative intimal lesions may occur in the young infant but are more common in the older child and adult.

Volume of the left atrial chamber approximates 50% of normal[20,72] due to the absence of that volume contributed by the common pulmonary vein. The ventricular cavity size and left ventricular volume is decreased,[72,73] although the mass of the left ventricle is normal.[73] The decrease in left ventricular cavity size is due largely to the abnormally displaced interventricular septum and the chronic decrease in left ventricular preload. Systemic cardiac output, when measured, is usually low due to inadequate preload and a decrease in left ventricular ejection fraction.[21,72,73]

Systemic oxygen saturation in most patients is 85 to 90%, re-

flecting a large pulmonary blood flow in the setting of complete admixture of pulmonary and systemic venous return. Oxygen saturation in the pulmonary artery may be significantly greater than that found in the femoral artery in patients with supracardiac and cardiac anomalous venous connections. This difference may be due to the streaming effect of inferior vena caval blood through the foramen ovale with pulmonary venous blood returning through either the SVC, right atrium, or coronary sinus being preferentially directed across the tricuspid valve.[71,66]

TAPVC with a Nonrestrictive Interatrial Communication

A nonrestrictive IAC occurs in approximately 20% of patients with uncomplicated TAPVC. In the absence of obstruction in the extracardiac pulmonary venous channels, these patients usually exhibit hemodynamic findings and clinical symptoms different from the above two groups.

The nonrestrictive interatrial communication allows free communication between the two atria and, under these conditions, the distribution of mixed venous blood is determined by the relative compliance of the atria and ventricles and on the relative resistances in the pulmonary and systemic arterial circulations.

The systemic blood oxygen saturation in this "total mixing lesion" is dependent, for the most part, on the pulmonary blood flow. Since in most circumstances the systemic blood flow is 3 L/min/m^2, this is the systemic venous return that mixes with the pulmonary venous return: the higher the pulmonary blood flow (and, therefore, pulmonary venous return) the closer to the pulmonary venous saturation will be the "totally mixed" blood that passes across the IAD into the left side of the heart and out the aorta. For example, if we assume for this purpose that the mixed venous O_2 saturation is 65% and the systemic blood flow is 3 L/min, then if the pulmonary blood flow is 3 L/min, the systemic O_2 saturation (mixing equal parts of 95% and 65%) is 80%; if the pulmonary blood flow is 6 L/min, the systemic O_2 saturation is 85%.

Although a large left-to-right shunt invariably develops, pulmonary artery pressures are usually normal or only mildly elevated.[71,74] The severe hemodynamic disruption and clinical symptoms seen in patients with a restrictive IAC usually are not observed. The gross pathologic changes as previously described in patients with a restrictive IAC occur but are less striking. A number of these patients will have a clinical course not unlike that of a large atrial septal defect in which signs of right heart failure and/or pulmonary hypertension may not develop until after the third or fourth decade of life.

Clinical Features

The natural history of clinical signs and symptoms and the subsequent hemodynamic observations in patients with TAPVC can be related to the previously described pathophysiologic categories.

TAPVC with Obstruction in the Anomalous Pulmonary Venous Channel

Signs and Symptoms. Infants born with obstruction in the anomalous pulmonary venous channels develop symptoms shortly after birth or within the first day or two of life. Cyanosis and respiratory distress usually occur early and may be severe. In patients with anomalous connection below the diaphragm, feeding may acutely worsen symptoms of cyanosis and dyspnea due to increased intraabdominal pressure or possibly impingement of the dilated esophagus on the common pulmonary vein as it traverses the esophageal hiatus. Severe pulmonary hypertension leads to progressive decrease in pulmonary blood flow and severe hypoxemia. If not treated, most infants die in the first few days or weeks of life, although some may live for 3 to 4 months.[60]

Physical Examination. Physical examination reveals a severely cyanotic infant with moderate to marked respiratory distress. The heart is not enlarged clinically, although there is usually a prominent right ventricular impulse, which suggests pulmonary hypertension. The pulmonic component of the second heart sound may be accentuated, and there may be a third or fourth heart sound audible over the left lower sternal border. Murmurs are infrequent and, when present, usually are detected over the pulmonary outflow tract. The murmur of tricuspid insufficiency may be appreciated due to right ventricular hypertension. Peripheral pulses are usually of normal amplitude shortly after birth but may weaken as progressive cardiac failure ensues. Hepatomegaly is present and often quite dramatic in patients with anomalous pulmonary venous connection to the portal venous system.

Electrocardiogram. Right ventricular hypertrophy is observed in the majority of patients with obstructed TAPVC, usually manifested by a qR pattern in the right chest leads. In addition, many patients exhibit a paucity of left ventricular forces in the left precordial leads. Right atrial enlargement is rare.

Radiographic Features. The chest roentgenogram may be quite helpful in determining the presence or absence of obstruction to pulmonary venous return in patients with suspected TAPVC.[75] The cardiac size is usually normal or only mildly increased. Pulmonary vascular markings, however, are abnormal and are characterized by a diffuse, linear reticular pattern radiating from the hilar regions (Fig. 69–9). Overt pulmonary edema with Kerley B

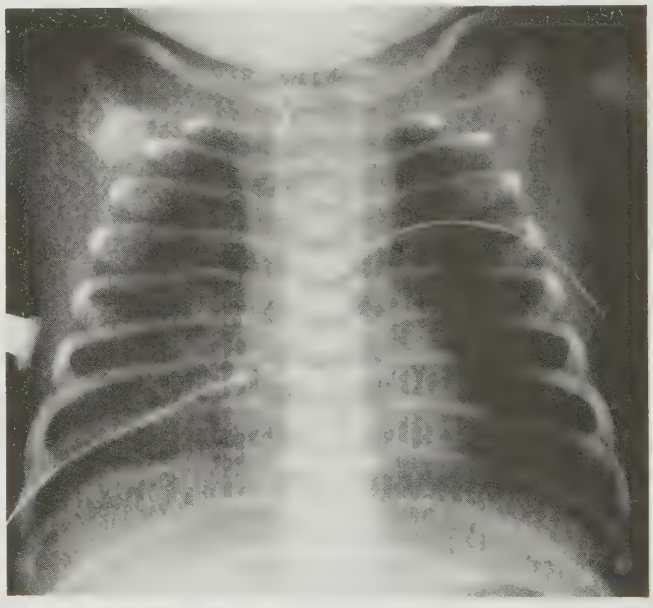

Fig. 69–9. TAPVC with obstruction. The heart size is normal, and the lungs are hyperinflated. Pulmonary vascularity demonstrates a diffuse, linear reticular pattern radiating from the hilum, which represents pulmonary venous engorgement and lymphatic distension.

lines may be present with perihilar congestion, which results in obscured cardiac borders. Hyperinflation of the lungs may be seen, which should differentiate this cardiac anomaly from early hyaline membrane disease. In addition, the normal to increased pulmonary vascularity helps distinguish this entity from persistent fetal circulation syndrome.

TAPVC with a Restrictive Interatrial Communication

Signs and Symptoms. These patients are usually asymptomatic at birth and during the first few weeks of life. When signs or symptoms are detected during this period, they are usually mild cyanosis with crying or mild tachypnea during feedings. As pulmonary blood flow increases and the interatrial communication becomes restrictive, symptoms of progressive tachypnea, respiratory distress, feeding difficulties and cardiac failure occur. These symptoms usually develop after the first month of life and lead to medical consultation in the second month. In the absence of medical or surgical intervention, progressive cardiac failure complicated by pulmonary infections occurs, which is fatal in 75 to 85% of these infants prior to 1 year of age.[64,76]

Physical Examination. In symptomatic infants, failure to thrive, resting tachypnea, and mild perioral duskiness are observed. Overt cyanosis may be absent due to relatively high arterial oxygen saturations. There is a prominent right ventricular lift and a hyperdynamic precordium. Auscultation reveals a loud first heart sound and at times a systolic ejection click. The second heart sound usually is widely split and fixed and the pulmonary component is often accentuated. An S3 gallop over the left lower sternal border and apex may be detected, and a fourth heart sound may be heard as well.

A low-frequency systolic murmur of Grade I to II in intensity representing increased pulmonary flow usually is heard over the left upper sternal border. In addition, there is a tricuspid diastolic murmur at the left lower sternal border in approximately 50% of patients.[76] Occasionally, a continuous venous hum may be detected in an area overlying the anomalous venous connection. This murmur has been found most commonly in patients with supracardiac TAPVC and is distinguished from the innocent venous hum by its lack of variation with change in position or jugular venous pressure. Hepatomegaly is usual, and peripehral edema often is observed.

Electrocardiogram. Right axis deviation, right atrial enlargement, and right ventricular hypertrophy are seen in most patients who are symptomatic. The electrocardiogram is often normal in patients in the first week of life, reflecting the minimal hemodynamic disturbance at this stage.[71]

Radiographic Features. The chest roentgenogram may be normal in the first week of life.[71] When symptoms develop, the heart size is moderate to markedly increased with cardio-thoracic ratios between 0.60 and 0.70.[77] This enlargement is due to right atrial and right ventricular dilatation. The pulmonary vascularity is increased diffusely, and there is dilatation of the hilar and midlung vessels.

Distinctive radiographic features may be observed, reflecting the course of the anomalous pulmonary venous channel. The classic figure-eight or "snowman" sign in TAPVC to the left innominate vein may be seen in the older infant and child (Fig. 69–10), although it has been observed in patients as young as 4 months of age.[78] The right superior mediastinum may be prominent in

Fig. 69–10. Supracardiac TAPVC. Chest radiograph in a child with connection to the left innominate vein demonstrating increased pulmonary vascularity and the figure-eight or "snowman" appearance. Arrow points to anomalous vertical vein.

cases of TAPVC to the superior vena cava. Gott and associates[79] described the radiographic feature of horizontal takeoff of the left border of the heart below the aortic arch. This box-like appearance was due to massive enlargement of the right atrium and right ventricle with the latter structure forming most of the upper left border of the cardiac silhouette.

TAPVC with a Nonrestrictive Interatrial Communication

Signs and Symptoms. Patients with a nonrestrictive interatrial communication exhibit a different pattern of clinical symptoms. When symptoms develop in the first year of life, they consist of mild failure to thrive, exertional dyspnea, and recurrent pulmonary infections. Clinical cyanosis is rare in the first 1 or 2 years of life but may become apparent in the older child or young adult with the development of right heart failure or, rarely, pulmonary vascular obstructive disease.

Physical examination and cardiac auscultatory findings may be similar to those just described in patients with a restrictive interatrial communication or may mimic more closely those observed in a large atrial septal defect. Electrocardiography demonstrates right atrial enlargement and right ventricular hypertrophy. Radiographic findings include mild to moderate cardiomegaly with increased pulmonary vascularity and the radiographic appearance of the specific anomalous venous channel as discussed previously.

In summary, patients with TAPVC and a nonrestrictive interatrial communication have signs and symptoms that fall between, on the one hand, patients with a large uncomplicated atrial septal defect and, on the other, those with TAPVC with a restrictive IAC and congestive heart failure.

Diagnostic Techniques

Echocardiography

The M-mode echocardiographic findings in TAPVC include moderate to marked dilatation of the right ventricle, paradoxical ventricular septal motion and, on occasion, demonstration of an

echo-free space posterior to the left atrium representing the pulmonary venous confluence.[80,81] High-resolution real-time two-dimensional echocardiography with Doppler capabilities has extended this modality to the degree that precise anatomic and functional characterization of each type of TAPVC can be accomplished in many cases.

Two-dimensional imaging of the anomalous pulmonary venous pathways has now been well described.[82–85] The development of multiple imaging planes to reconstruct the course and connections of the anomalous pulmonary venous channels has led to precise anatomic localization that may, in selected cases, obviate the need for invasive cardiac catheterization.

The parasternal long axis scan may reveal the confluence of the pulmonary veins posterior to the left atrium, or it may detect a prominent coronary sinus (Fig. 69–11). Right ventricular enlargement with septal displacement to the left and enlarged pulmonary arteries are common. Apical and subcostal four-chamber views may demonstrate the individual pulmonary veins connecting to the confluence and the subsequent entrance to the right atrium or coronary sinus. Subcostal transverse and sagittal scans of the abdomen are used to image the descending vein in patients with infradiaphragmatic TAPVC[82] (Fig. 69–12). Suprasternal scanning, using long and short axis planes, is useful in detection of the pulmonary venous confluence in supracardiac TAPVC. However, mapping the course of the subsequent drainage often requires multiple projections (Fig. 69–13). The suprasternal short axis scan may be used to detect the points of insertion of the individual pulmonary veins into the venous confluence in patterns with infradiaphragmatic TAPVC.

Using a standardized sequential technique with imaging in multiple planes as just described, Huhta et al.[70] prospectively detected the presence of TAPVC in 33 of 34 patients undergoing cardiac catheterization (97% sensitivity). However, the exact type of TAPVC and the site (or sites) of anomalous connection was accurately predicted in only 71%. Errors in localization of the anomalous pulmonary venous connection occurred in circumstances of abnormal atrial situs associated with complex congenital heart disease and in patients with mixed type TAPVC.

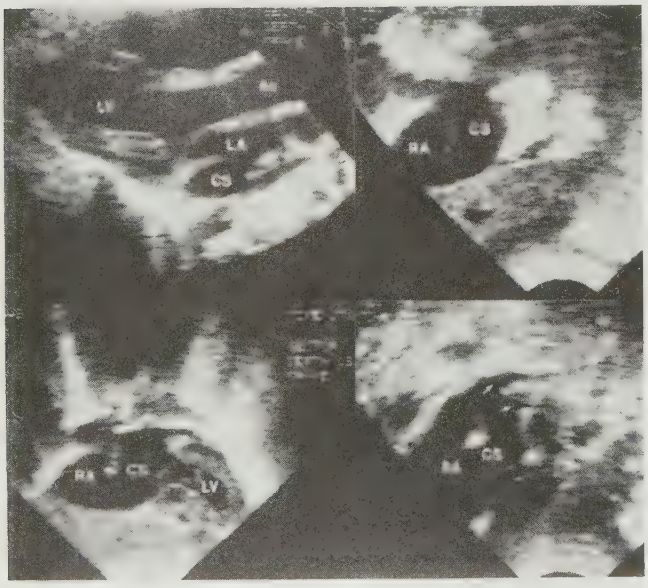

Fig. 69–11. Ultrasonic imaging of total anomalous pulmonary venous connection to the coronary sinus. Long axis scans show a markedly dilated coronary sinus behind the left atrium (left upper panel). Imaging of the entry of the pulmonary veins into the coronary sinus (white arrows) is possible from subcostal scans. (Reprinted with permission from Huhta, J.C.: Pediatric Imaging/Doppler Ultrasound of the Chest. Philadelphia, Lea & Febiger, 1986, p. 155, Figure 10–8, from Br. Heart J., *53*:525, 1985.)

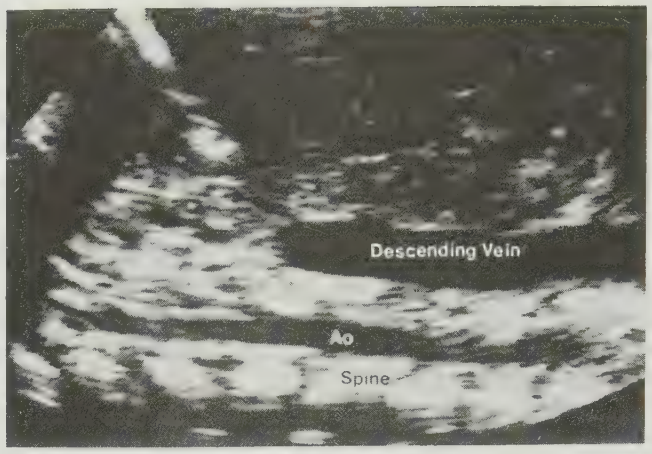

Fig. 69–12. Sagittal scan of the abdomen showing the descending aorta, spine, and more anterior descending vein entering the liver. (Reprinted with permission from Huhta, J.C.: Pediatric Imaging/Doppler Ultrasound of the Chest. Philadelphia, Lea & Febiger, 1986, p. 158, Figure 10–11.)

The addition of both pulsed and continuous-wave Doppler ultrasound has enhanced diagnostic accuracy of two-dimensional imaging alone. Stephenson et al.[86] used pulsed Doppler echocardiography from the parasternal and suprasternal planes to diagnose supracardiac TAPVC to the innominate vein. The Doppler flow pattern consisted of nonphasic disturbed flow posterior to the left atrial line detected by the M-mode technique. Stephenson et al. observed that the abnormal flow pattern differed from left atrial flow in its directionality (away from the heart) and its characteristic poor variation with changes of cardiac cycle. This characteristic Doppler flow pattern has now been used to detect all types of TAPVC, both above and below the diaphragm.[87,88] Smallhorn and Freedom[89] described the Doppler flow pattern observed in TAPVC with extracardiac obstruction as nonphasic and varying only with respiration. Vick et al.[90] thought that a disturbed venous flow pattern with a peak velocity of greater than 2 m/s occurring in diastole at the site of narrowing was associated with significant obstruction to pulmonary venous return.

Radionuclide Angiography

Radionuclide imaging has been used in the noninvasive assessment of TAPVC.[91] In four patients with infradiaphragmatic TAPVC, rapid recirculation through the right atrium occurring 3 to 6 seconds after the initial passage of radionuclide was recorded. In addition, direct visualization of the anomalous common pulmonary trunk was observed in three of four patients. In these patients, this technique was helpful in differentiating TAPVC from persistent fetal circulation. First-pass radionuclide angiography may aid the preoperative quantitation of pulmonary to systemic

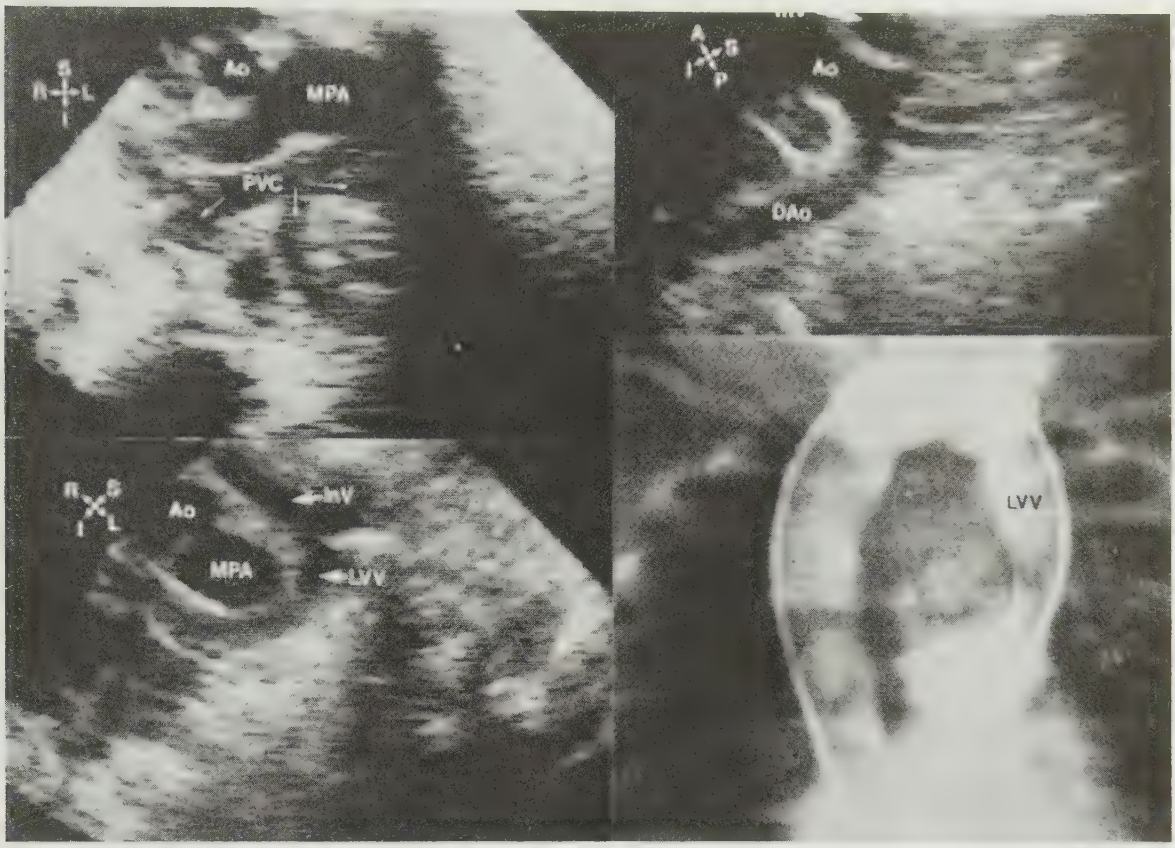

Fig. 69–13. Total anomalous pulmonary venous connection to a left vertical vein in an infant. Suprasternal scans reveal the entry of the four pulmonary veins to the pulmonary venous confluence (PVC) (left upper panel), and segmental imaging of the vertical vein and innominate vein (InV) confirm the diagnosis. An angiogram with the catheter in the left vertical vein (LVV) is shown for comparison (right lower panel). blood flow ratios and the postoperative assessment of residual defects and ventricular function.

Cardiac Catheterization

Catheter Course. The catheter course in combination with oxygen-saturation data may be diagnostic of TAPVC if the anomalous pulmonary venous channel is entered directly. This can be accomplished usually with connection to the right atrium and coronary sinus as well as supracardiac connection to the left innominate vein. Catheter manipulation into the anomalous connection to the superior vena cava may be difficult due to the acute angle of insertion of the anomalous vein and the high frequency of obstruction that occurs in this type of connection. Although rare, the descending anomalous venous connection in patients with infradiaphragmatic TAPVC may be entered during catheter manipulation through the umbilical vein.

Saturations. Sampling of blood in the right atrium usually reveals oxygen saturations above 90%. Although one would expect saturations to be nearly identical in all cardiac chambers and great vessels distal to the right atrium, we[71] and others[66,92,93] have noted significant differences in the pulmonary arterial and systemic arterial oxygen saturations in many patients. In cases of cardiac or supracardiac TAPVC, pulmonary venous blood is directed preferentially across the tricuspid valve whereas inferior vena caval flow is directed across the foramen ovale; this leads to significantly lower saturations in the systemic arterial circulation when compared to those found in the pulmonary artery. Conversely, significantly higher oxygen saturations may be found in the systemic arterial system in patients with infradiaphragmatic TAPVC. Oxygen tensions (Pa_{O_2}) as high as 250 mm Hg have been described in patients breathing 100% oxygen with infracardiac TAPVC due to this streaming effect.[93,94] Such high saturations may be misleading and may erroneously suggest the diagnosis of persistent fetal circulation or primary pulmonary disease.

Hemodynamic Data. In patients with severe obstruction in the extracardiac pulmonary venous channels, pressures in the right ventricle and pulmonary artery are equal to or greater than systemic. Pulmonary artery wedge pressure is elevated, in contrast to the relatively normal or low left atrial pressure. Right atrial pressure is usually normal although it may be elevated. Entering the common pulmonary venous channel directly with a slow pullback pressure tracing often reveals a discrete pressure gradient at the site of obstruction.

Patients with a restrictive IAC have elevated pulmonary artery pressures that range from 50% to 100% of systemic pressure.[71] This pulmonary hypertension is of the high flow–low resistance type and can be reduced significantly by creating an adequate interatrial communication (Fig. 69–14). The right atrial mean and phasic pressures may be elevated over those found in the left atrium. In these cases, a restrictive interatrial communication is

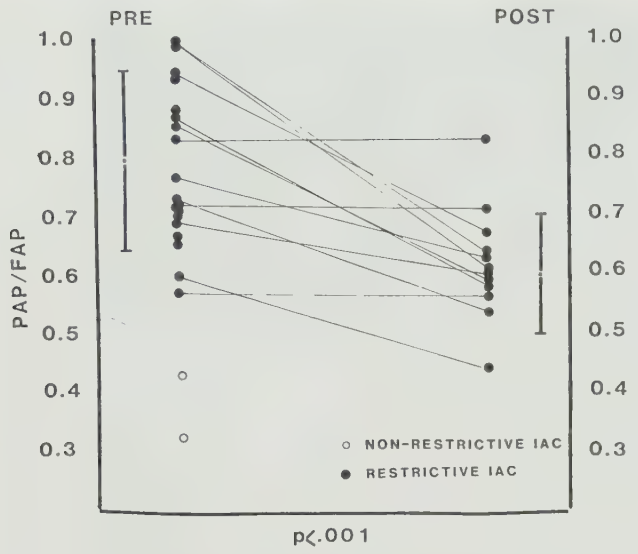

Fig. 69–14. Atrioseptostomy in TAPVC with a restrictive interatrial communication. The systolic pulmonary artery (PAP) to femoral artery (FAP) pressure ratio decreases significantly after an adequate septostomy. (Reprinted with permission from Ward, K.E., et al.: Restrictive interatrial communication in total anomalous pulmonary venous connection. Am. J. Cardiol., *57*:1131, 1986.)

diagnosed easily. When the atrial pressures are nearly equal, our experiences[71,92,95] and that of others[69] suggest that there still may be significant obstruction at the atrial septum. This phenomenon likely is related to several factors, including: 1) the greater capacitance of the right atrium as compared to the left[92]; 2) the possibly comparable compliance of the two ventricles and thus their equal respective filling pressures; 3) the technical difficulty of detecting transient, phasic pressure differences in patients with rapid heart rates using standardized fluid-filled catheter systems. To rule out completely a restrictive interatrial communication, measurement of the size of the atrial defect is mandatory and is accomplished by slow withdrawal of a calibrated septostomy balloon from left atrium to right atrium. An interatrial communication less than 10 mm by this method should be suspected as being restrictive.[71]

Intermediate degrees of obstruction in the pulmonary venous channels may exist and may be related to the length of the anomalous channel. This situation occurs commonly in TAPVC to the left innominate vein in which a gradual mean pressure gradient as great as 12 mm Hg may be recorded between the common pulmonary vein and right atrium. Although a number of these patients may respond favorably to balloon septostomy, 50% of the infants in our study with this anatomic variant failed to demonstrate adequate relief of symptoms after septostomy and required early surgical repair.[71]

Angiography. Selective right and left pulmonary arteriography is the initial angiogram performed in most patients with suspected TAPVC. On the levophase, collection of the contrast material in the pulmonary venous channels usually demonstrates the site of connection and areas of potential obstruction.

In patients with obstructed TAPVC and severe pulmonary hypertension, pulmonary angiography may be difficult because of prominent right-to-left shunting through the ductus arteriosus. Under these circumstances, balloon occlusion of the ductus during angiography may be used to enhance visualization of the anomalous venous connections. With severe obstruction, circulation time through the lungs is prolonged, and contrast material is slow to fill the pulmonary venous circuit, thereby resulting in poor opacification. In these cases, direct injection in the pulmonary artery wedge position through an end-hole catheter has been used to enhance definition of pulmonary venous anatomy.

With manipulation of the catheter directly into the anomalous venous channels, angiography can be more rewarding and detect abnormalities not observed during follow-through pulmonary arteriography.

Balloon Atrioseptostomy. Although some investigators feel that significant obstruction at the atrial level (restrictive IAC) is rare in TAPVC,[66] we[71] and others[64,69] have found hemodynamic or anatomic evidence of a restrictive IAC in 70 to 80% of patients with uncomplicated TAPVC. Creation of a large IAC by open septectomy[74] or balloon/blade septostomy[71,92,95–97] is effective in improving hemodynamics and clinical symptoms in most patients with congestive heart failure due to a restrictive IAC.

If a significant atrial pressure difference exists, septostomy results in equalization of mean and phasic pressures in most cases. In addition, the pulmonary artery/femoral artery pressure ratio is reduced significantly due to both a decrease in pulmonary arterial blood flow and an increase in systemic flow. These favorable alterations persist in longterm followup studies, and the pulmonary artery/femoral artery pressure ratio may show progressive reduction over that observed in the early postseptostomy period. Clinical improvement occurs in most patients and may be dramatic in some.

Performing balloon/blade septostomy in TAPVC is challenging due to the small size of the left atrium and the absence of normal left atrial landmarks (pulmonary veins, high oxygen saturations). In addition, rapid inflation and pullback must be performed since the inflated balloon obstructs the entire systemic output. Echocardiographic imaging during balloon placement and inflation has been helpful in this regard.

Differential Diagnosis

In newborn infants with obstructed TAPVC, the differential diagnosis includes other causes of pulmonary venous obstruction (atresia of the common pulmonary vein, pulmonary vein stenosis, cor triatriatum), hypoplastic left heart syndrome, tricuspid and pulmonary atresia, interruption or coarctation of the aorta, transposition of the great vessels, hyaline membrane disease, and persistence of the fetal circulation. Differentiating TAPVC with obstruction from these other entities has improved dramatically with the advent of two-dimensional and pulse Doppler echocardiography.

Beyond the newborn period, TAPVC with or without a restrictive interatrial communication may mimic a number of congenital cardiac lesions including large ventricular septal defect, truncus arteriosus, complete atrioventricular canal defect, and single ventricle without pulmonary stenosis. Older patients with minimal or no symptoms will have findings that may suggest a large atrial septal defect, common atrium, or partial anomalous pulmonary venous connection.

Natural History

In untreated patients, the prognosis in TAPVC is determined by the presence or absence of obstruction in the extracardiac pul-

monary venous channels and the size of the interatrial communication. Infants presenting in the first few days of life with severe symptoms of pulmonary venous obstruction usually die within the first month of life. Those who survive this period often have lesser degrees of obstruction or have developed alternate pathways of pulmonary venous return.

Infants who die in the first week of life show similar gross pathologic and histologic changes.[60] The right atrium and right ventricle may appear normal, or they may show varying degrees of dilation and hypertrophy. Histologic sections of the lung reveal thickening of the alveolar walls due to massive capillary dilation and interstitial edema. Hemosiderosis is common, and lymphatic channels in the visceral pleura and interlobular septa are dilated (Fig. 69–15). The intrapulmonary arterial and venous vessels reveal increased muscularity due to marked medial hypertrophy. These findings have been observed as early as 1 day of age, which suggests a prenatal damage to the pulmonary vascular bed in patients with severe obstruction in the anomalous venous channels.[98] This dramatic muscularity has been implicated in the development of acute reversible pulmonary hypertrophy that has been observed early after repair in some infants.

Patients developing symptoms due to a restrictive interatrial communication have a prognosis not much better than that just described. Eighty percent of such infants will likely die by 1 year of age, with the majority dying in the first 6 months of life.[64,76] The cause of death is persistent severe congestive heart failure in the setting of chronic malnutrition and recurrent pulmonary infections.

In patients who are well palliated after atrial septostomy or who have a large atrial septal defect, the natural history varies. Some patients may have slight symptoms and complain only of dyspnea with exertion and exercise intolerance. Others may develop cyanosis in the second and third decade due to progressive right heart failure or pulmonary vascular disease.

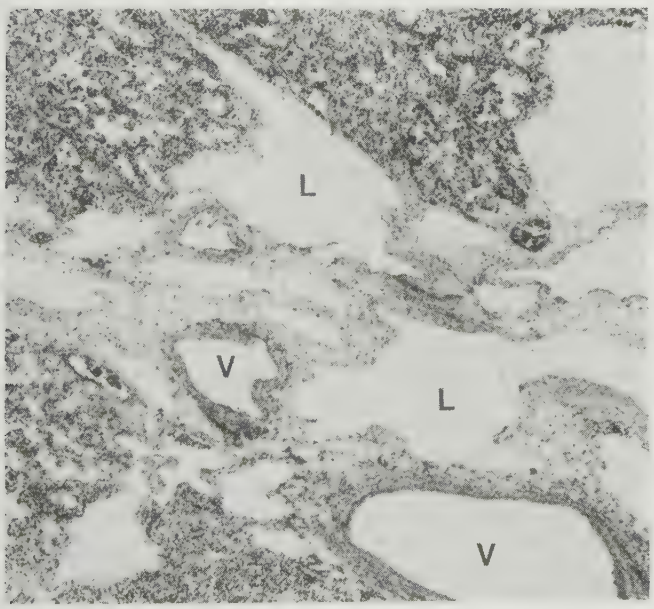

Fig. 69–15. Histologic pathology in obstructed anomalous venous connection. In a typical pulmonary septum, there are increased numbers of dilated lymphatic channels (L) as well as distended, muscularized pulmonary veins (V). Hematoxylin and eosin stain, ×40. (Courtesy of Sarah F. Johnson, M.D.)

Although pulmonary hypertension is common in patients with obstructed extracardiac anomalous venous channels or a restrictive interatrial communication, severe advanced pulmonary vascular obstructive disease (plexogenic pulmonary arteriopathy) occurs infrequently.[99,100,101] Although some investigators have disagreed on this point,[102] the postoperative hemodynamic studies support this contention.[69,71,72,103]

Treatment

In infants with TAPVC who present with marked cyanosis, respiratory distress and cardiovascular collapse in the first few days of life, severe obstruction in the extracardiac pulmonary venous channels must be assumed. Under these circumstances, cardiorespiratory and metabolic stabilization should be instituted rapidly. This may include mechanical ventilation, inotropic support and correction of acid–base or metabolic derangements. Experimental evidence[104] and one clinical report[105] suggest that prostaglandin E1 may dilate the ductus venosus and thus enhance pulmonary venous return in patients with TAPVC to the portal venous system.

After stabilization, definitive diagnostic study should be undertaken to define the connection of the anomalous pulmonary venous channel or channels. High-resolution two-dimensional echocardiography with Doppler interrogation has been used as the sole diagnostic procedure prior to emergency surgical intervention in some patients.[83,106] Precise delineation of the anomalous venous connection in patients with a mixed type of TAPVC or in those with complex associated anomalies (asplenia syndrome) may be more difficult,[85,107] and in these cases cardiac catheterization with selective angiography is advisable.

Although most investigators agree that urgent surgery is indicated in all cases of TAPVC with severe extracardiac obstruction, controversy exists in the management of those patients without severe extracardiac obstruction, most of whom present after the early newborn period. In our series of 21 patients with TAPVC without extracardiac obstruction, we performed balloon or blade/balloon atrial septostomy at the time of diagnosis followed by aggressive medical therapy and close followup.[71] Seventy-five percent of these patients were well palliated and underwent elective surgical repair in the second year of life with a mortality of 5%. The others required surgical intervention because of persistent severe congestive heart failure and failure to thrive. The morbidity and mortality observed in our patients compares favorably with recent results of surgical correction at the time of diagnosis.[103,108,109] Circumstances that may dictate an early palliative approach with later total correction include 1) some cases of mixed type TAPVC in which multiple small anastomoses between the pulmonary veins and the left atrium would be required; 2) patients with severe circulatory compromise because of a restrictive interatrial communication in whom the operative mortality would be better if repair could be delayed; and 3) infants unable to undergo cardiopulmonary bypass requiring blood prime because of parental religious convictions.[71]

Surgical Technique

The first attempt at surgical repair of this lesion was by Muller[15] in 1951; partial correction was achieved with the use of a closed

anastomosis between the left atrial appendage and the left upper pulmonary vein. In 1954, Burroughs and Kirklin[16] successfully repaired a cardiac TAPVC by means of the atrial well technique. One year later Lewis and Varco,[17] using moderate hypothermia and inflow occlusion, successfully repaired a cardiac-type TAPVC. Cooley and Ochsner[18] performed the first successful correction of TAPVC using cardiopulmonary bypass with a transatrial approach and an open anastomosis. In 1964, the posterior approach was introduced by Williams[110] and remains the procedure of choice at the Texas Heart Institute.[111] Other centers[69,112] continue to use a modification of the original transatrial approach of Cooley because of difficulties with distortion of the anastomosis that may occur when the heart is displaced from its anatomic position. In the majority of newborn and very young infants, deep hypothermia with circulatory arrest often is used to perform the repair. In older infants, normothermic cardiopulmonary bypass using cold potassium cardioplegia for myocardial protection has been used with equally good results.[71]

Surgical approaches for the specific anomalies follow:

TAPVC of the Supracardiac or Infracardiac Type. Either a right transatrial or a posterior approach is used in these circumstances (Fig. 69–16). The common pulmonary vein is mobilized, and the ascending or descending vein is ligated. Creation of a large side-to-side anastomosis between the left atrium and common pulmonary vein is then performed, often using an incision in the left atrium that runs from the left atrial appendage into the right atrium to maximize left atrial volume. The interatrial communication is then closed with pericardium or prosthetic material.

Cardiac Type TAPVC. A right atrial approach is used, and in the case of TAPVC to the right atrium, the interatrial septum is excised completely and a pericardial or prosthetic patch is sutured to close the atrial septal defect and direct all of the pulmonary venous return into the left atrium. When the pulmonary venous connection is through the coronary sinus, the partition between the coronary sinus and the right atrium is excised along with the interatrial septum. A septum is then fashioned with pericardium or prosthetic material to direct the pulmonary veins into the new left atrium (Fig. 69–17). Using this technique, the coronary sinus veins are identified and the patch is sutured behind these veins in order to direct coronary sinus return to the right atrium. Some surgeons prefer to use wide excision of the common wall between the left atrium and coronary sinus without enlarging the ASD. In this instance, the ASD and coronary sinus orifices are closed by direct suturing so that coronary venous blood returns to the left atrium. This mild desaturation is clinically inapparent and well tolerated.

Surgical Results

Operation for correction of TAPVC in newborns and young infants was associated with a high mortality during the early years of infant cardiac surgery. Mustard et al.[112] reported no survivors in attempted total correction in 1962, and Cooley and associates[113] experienced a 54% mortality up to 1966. Survival improved in the 1970s with two large centers reporting an operative mortality of 36%.[114,115] This improvement in operative survival was linked to a number of factors including: 1) earlier recognition and prompt referral; 2) complete diagnosis using cardiac catheterization and angiocardiography; 3) aggressive preoperative medical management; 4) total correction using deep hypothermia and circulatory arrest to enhance construction of a large anastomosis in a bloodless operative field; and 5) intensive postoperative management, including strict attention to fluid balance and aggressive treatment of pulmonary complications.[114]

Despite improvement in overall operative results during this period, mortality remained high in infants less than 6 months of age. This led some centers to recommend aggressive medical management (including balloon septostomy) in hopes of delaying surgery until after the first 6 months of life[92,115] in those patients without extracardiac obstruction. Other investigators found determinants of early survival to be unrelated to age per se, but rather to the anatomic type of TAPVC,[108,114,116] the presence of pulmonary hypertension related to intracardiac or extracardiac obstruction,[103,108,109,117] and the patient's clinical status at the time of presentation.[103,112,117] For these reasons, many centers have adopted the approach of urgent surgical intervention shortly after diagnosis in all patients, whether there is severe obstruction or not. Using this approach, operative mortality has ranged from 8 to 13%.[107,108,117] Most of these patients had supracardiac or cardiac TAPVC. In fact, Mazzucco, et al.[109] reported no deaths in patients with TAPVC of the supracardiac and cardiac type. These results are encouraging and have led other centers to adopt a similar approach.

Unfortunately, operative mortality in those patients with infracardiac TAPVC or in patients with complex cardiac lesions in association with TAPVC remains high, ranging from 14 to 67%.[108,109,117]

Long-term Results

The long-term outlook in patients surviving correction of TAPVC is excellent. This is reflected in reported postoperative hemodynamic and angiographic studies. Pulmonary artery pressures are found to be normal or only mildly elevated in most cases;[21,71,103,117] the elevation is usually due to an increase in the pulmonary artery wedge pressure rather than increased calculated pulmonary arteriolar resistance. The elevation in pulmonary artery wedge pressure is found commonly and is considered due to mild anastomotic obstruction. Angiographically, however, the anastomosis usually appears widely patent in these patients with rapid emptying of contrast material from the pulmonary veins, thereby suggesting this obstruction has no functional significance.[69] The abnormalities in left ventricular size and function observed preoperatively become normalized in most patients[21,72,103,118] (Fig. 69–18), and right ventricular size returns to normal as well.

Reoperation after repair of total anomalous pulmonary venous connection has been reported in up to 20% of cases. Anastomotic obstruction may occur in all types of TAPVC and has been linked to the operative approach and the surgical technique employed.[119–121] The use of continuous nonabsorbable suture material for construction of the anastomosis may be responsible for some causes of late obstruction. This has led to the recent use of a newly developed, stronger absorbable monofilament suture material (polydioxanone) for construction of the anastomosis. Although short-term results have been encouraging,[121] long-term results are not known. A more difficult problem arises when obstruction occurs proximal to the anastomotic site in the pulmonary veins themselves. This complication appears to be more common in infradiaphragmatic TAPVC[108,119,120] but has been found in other types of lesions, most commonly anomalous connection to the coronary sinus.[68,121] This obstruction is due to partial or complete obliteration of the ostia of the pulmonary veins by fibrosis similar to that lesion

found in isolated stenosis of the pulmonary veins. Results of reoperation for this complication are uniformly poor.[108,121]

Late arrhythmias may develop in a small number of patients after operative correction of TAPVC. Atrial arrhythmias are most common and include sinus bradycardia as well as supraventricular tachycardia and atrial flutter. Ventricular arrhythmias are rare.

The Future: Prenatal Diagnosis

Recent advances in fetal echocardiography have led to the prenatal diagnosis of a number of congenital cardiac defects.[122,123] Abnormalities in pulmonary venous connection, however, have not yet been described. The difficulty with prenatal diagnosis of abnormalities in pulmonary venous connection is likely due to a number of factors including the relative infrequency of abnormalities in pulmonary venous connection in the spectrum of congenital heart disease, the lack of a "genetic predisposition" for the development of this anomaly, and normal fetal blood flow patterns that mask abnormalities in pulmonary venous anatomy and function. The prenatal detection of infradiaphragmatic TAPVC would be expected to increase the chances of survival if surgery were performed shortly after delivery prior to the development of severe symptoms. Recent work in the area of intrauterine cardiothoracic surgery in the fetal lamb[124] suggests that prenatal correction of congenital cardiac defects, including abnormalities of pulmonary venous connection, may be feasible in the near future.

STENOSIS OF THE INDIVIDUAL PULMONARY VEINS

Stenosis of one or more of the individual pulmonary veins in the absence of anomalous pulmonary venous connection is rare. Reye[125] reported in 1951 the autopsy findings on an 8-year-old patient who died with severe stenosis of three pulmonary veins and atresia of the fourth. Bini et al.[126] reviewed 38 cases reported up to 1984 and added 10 of their own. In Bini et al.'s 10 cases, all major pulmonary veins were obstructed; however, the type of obstruction and the severity of involvement was unique in each patient illustrating the wide spectrum of disease that may be encountered.

Embryology and Pathology

Edwards[127] has proposed that stenosis of the individual pulmonary veins is due to abnormal incorporation of the common pulmonary vein into the left atrium in the later stages of cardiac embryogenesis. This thesis is supported by the observations of Shone, et al.[128] and are enumerated as follows: 1) there is a frequent association with other congenital cardiac anomalies; 2) most patients become symptomatic in the first few years of life; 3) there is a similarity in the histopathologic lesion that occurs in normally inserting pulmonary veins and in those veins that insert into structures other than the left atrium (TAPVC); and 4) the absence of the active inflammation in or around the involved segments of vein.

The pathologic anatomy varies widely in both the number of pulmonary veins involved and in the degree of involvement. Three distinct types of pulmonary vein stenosis have been described (Fig. 69–19): 1) long-segment hypoplasia of a pulmonary vein that may extend into the lung parenchyma; 2) a discrete "diaphragm" occurring in the extrapulmonary veins;[129] or 3) focal or diffuse intimal fibrosis localized to the pulmonary vein ostia or extending some distance into the pulmonary veins. Diffuse, long-segment hypoplasia of the entire extraparenchymal vein is often found in patients with severe pulmonary artery stenosis or atresia and has been described in the hypoplastic left heart syndrome.[34] Discrete lo-

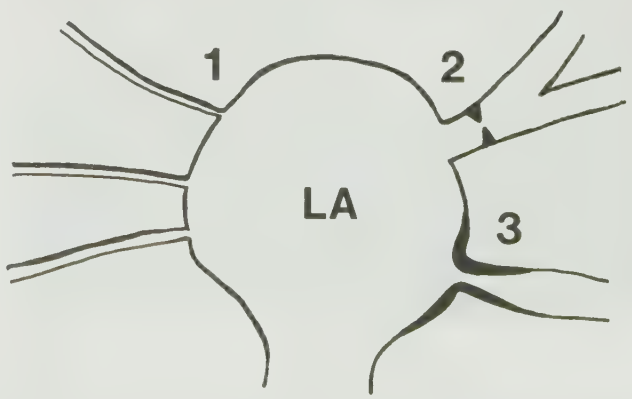

Fig. 69–19. Types of pulmonary vein stenosis. 1) Long segment hypoplasia. 2) Discrete diaphragm. 3) Focal intimal fibrosis.

calized obstruction at the veno–atrial junction is the most common pathologic process, and the gross and histologic findings are similar in all reported cases (Fig. 69–20).[126–128] There is nonspecific intimal thickening due to elastic and fibrous tissue proliferation with different degrees of irregularity of the media. The thickening is most prominent at the veno–atrial junction, but may extend some distance into the extraparenchymal pulmonary vein. All three types of obstructive lesions may occur in the same patient, although one is usually predominant.[126]

Associated cardiac defects occur in over 50% of patients with stenosis of the pulmonary veins, the most common being atrial and ventricular septal defects.[130] The pathologic cardiac findings observed in patients with pulmonary vein stenosis are similar to those found in other cardiac disease producing elevation of pulmonary venous pressure. Dilation of the intrapulmonary lymphatic channels and interstitial edema are present, and variable degrees of medial hypertrophy of the pulmonary veins occur. The pulmonary artery usually is dilated and thick-walled, and there is right ventricular and right atrial hypertrophy.

Clinical Features

Most patients present in the first few years of life with a long history of respiratory symptoms, including persistent tachypnea and recurrent pneumonia. There is often failure to thrive of a chronic nature interspersed with acute episodes of life-threatening pulmonary edema and right-sided cardiac failure. Hemoptysis may be a prominent symptom, especially in older children. Cyanosis may occur in patients with severe pulmonary edema, or in those with right-to-left intracardiac shunt. Physical examination reveals signs of pulmonary hypertension including a right ventricular lift, a loud pulmonary component of the second heart sound, and a nonspecific systolic murmur over the base. In addition, the murmurs of tricuspid and pulmonary insufficiency often are detected. Electrocardiography demonstrates right ventricular hypertrophy as well as right atrial enlargement in most cases.

Diagnostic Studies

Radiologic Features

The heart may be normal-sized or may demonstrate features of right ventricular hypertrophy and/or dilation, right atrial enlargement, and dilatation of the pulmonary artery. The characteristic reticular markings of pulmonary venous obstruction usually are present and may be unilateral or localized to a single pulmonary segment (Fig. 69–21). In addition, shift of the cardiomediastinal silhouette to the side of major involvement often is observed due to diminished arterial perfusion of the affected lung, leading to diminished pulmonary volume.[131] There may be increased arterial vascular markings in unaffected lung segments as a result of re-

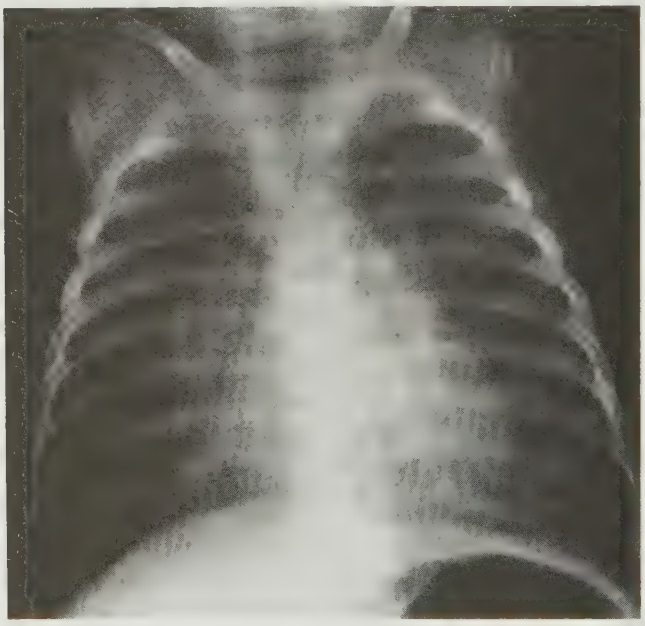

Fig. 69–21. Chest radiograph in pulmonary vein stenosis. There is mild hyperinflation of both lungs and mild cardiomegaly with straightening of the left heart border suggestive of right ventricular enlargement. The central pulmonary vascularity is indistinct due to perihilar congestion. Prominent pulmonary venous markings are apparent and most notable in the left lower lobe.

distribution of pulmonary blood flow away from the obstructed lobes.

Radionuclide Studies

In cases of predominantly unilateral pulmonary vein stenosis or atresia, there is a marked disparity in perfusion as demonstrated by radionuclide perfusion lung scans.[133] Radionuclide ventilation studies also may be abnormal showing underventilation of the affected lung due to decreased lung volume and poor compliance.[134]

Echocardiographic Features

The characteristic echocardiographic findings are those of severe pulmonary hypertension and include dilatation of the pulmonary artery, right ventricle, and right atrium and right ventricular hypertrophy. Doppler echocardiography demonstrates evidence of pulmonary hypertension and may reveal pulmonary and tricuspid valve insufficiency. Careful examination of the left heart structures should be performed to rule out other causes of pulmonary venous obstruction, including valve or supravalve mitral stenosis and cor triatriatum. Recently, pulsed Doppler sampling at the pulmonary vein/left atrial junction was used by Smallhorn[135] to detect pulmonary vein stenosis prior to cardiac catheterization. He was able to demonstrate a disturbed, high-velocity venous flow pattern at the ostia of the right upper pulmonary vein that was different from the normal pulmonary vein flow profile.

Cardiac Catheterization

Cardiac catheterization and cineangiography usually are diagnostic in this lesion, although the findings may be subtle and usually require a high index of suspicion. Suprasystemic pulmonary hypertension often is observed with elevation of pulmonary capillary wedge pressure ipsilateral to the side of obstructed pulmonary venous drainage.

In the case of unilateral obstruction, pulmonary arteriography reveals delayed circulation on the side of stenosis and diversion of blood away from the affected pulmonary artery, producing the "dead tree" appearance first described by Edwards.[127] Reversal of flow in diastole in the pulmonary artery of the ipsilateral lung may be observed as well. If precise anatomic details of the pulmonary venous anatomy are not obtained by pulmonary artery cineangiograms, selective right and left pulmonary artery wedge injections may be helpful.[126] Direct injection into the affected pulmonary vein has also been reported, although often the stenosis is so severe that even a small caliber catheter cannot be manipulated into the obstructed vein.

Differential Diagnosis

The differential diagnosis in patients with clinical findings of pulmonary hypertension include left heart obstructive lesions (mitral stenosis, cor triatriatum), idiopathic pulmonary hypertension, pulmonary veno–occlusive disease, constrictive pericarditis or mediastinitis, pulmonary venous phlebitis due to tuberculosis, or invasion of the pulmonary veins by tumor tissue.[128]

Prognosis and Therapy

Unless only a single pulmonary vein is involved, the prognosis in patients with this disease is grim. Most patients succumb to progressive right heart failure, recurrent hemoptysis, or pulmonary infection.

Attempts at correction of this cardiac defect have been unsatisfactory. Dilatation of the pulmonary veins by balloon catheter has been attempted with reports of short-term success; however, stenosis always recurs.[136,137] Surgical treatment of this lesion has been equally disappointing.[126,130,136] Techniques that have been used in the repair include simple excision of an obstructing diaphragm,[138] excision and venoplasty using pericardium[129] or prosthetic material,[126] simple excision and reimplantation of the pulmonary vein into the left atrium,[130] and creation of autologous atrial flaps to widen the venoatrial junction.[139] Although satisfactory relief of pulmonary vein obstruction has been documented early postoperatively by a decrease in pulmonary pressure and improvement in the angiographic appearance, re-stenosis has recurred in almost all cases reported. In the few reported cases in which re-stenosis did not recur early, the patients were older[138] or had significant pulmonary venous obstruction confined to only one lung.[129,139]

The poor prognosis in most patients with stenosis of the individual pulmonary veins suggests that alternative therapeutic modalities be investigated. One option presently being investigated in the animal model is the placement of an expandable intravascular stent at the site of venous obstruction. These stents appear to be well tolerated in short-term studies without evidence of disruption of the vessel wall or thrombosis.[140] Clinical trials of this therapeutic modality are forthcoming. An alternative approach would be that of heart/lung transplantation as has been used in patients with primary pulmonary hypertension.

ATRESIA OF THE COMMON PULMONARY VEIN

Atresia of the common pulmonary vein occurs when the individual pulmonary veins connect to a pulmonary venous confluence that ends blindly behind the left atrium. Under these circumstances, severe obstruction to pulmonary blood flow occurs shortly after birth leading to marked hypoxemia, acidemia, and in most cases, death in the first days or weeks of life. Lucas et al.[141] first coined the term *atresia of the common pulmonary vein* to describe the pathologic findings in three infants who died with this anomaly. Since that original description in 1962, 17 cases have been reported in the literature including the report by Khonsari et al.[142] in which the first successful surgical correction was achieved.

Embryology and Anatomy

The embryologic abnormality that has been postulated to occur in these infants is obliteration of the connection between the common pulmonary vein and left atrium after obliteration of the primitive pulmonary to systemic venous channels. This theory is supported by the findings of an atretic fibrous strand of tissue extending from one of the pulmonary veins to the right or left atrium,[141] or connecting the common pulmonary vein to a systemic vein.[143] Patency of the ductus arteriosus has been found in all patients, although other significant cardiac defects are uncommon.

The lungs are characteristically firm and congested, with prominent lobules outlined by edematous interlobular tissue and dilated lymphatic channels.[141] Microscopic examination reveals medial hypertrophy of both small pulmonary arteries and pulmonary veins reflecting longstanding prenatal pulmonary venous obstruction.

The alveoli may contain red blood cells and iron-containing macrophages.[141]

Hemodynamics

The altered hemodynamics observed are those of severe obstruction to pulmonary venous return. Pulmonary blood flow is markedly diminished and is diverted away from the pulmonary circuit through right-to-left shunting through the foramen ovale and ductus arteriosus. Profound hypoxemia ensues, leading to metabolic acidosis that is unresponsive to medical therapy. Although large channels for egress of pulmonary blood do not exist, small anastomoses between the bronchopulmonary veins and the systemic venous system account for some infants' survival into the second or third week of life.[141]

Clinical Features

Infants are usually born at term after an uncomplicated pregnancy and delivery. Tachypnea and cyanosis appear within 12 hours of age in all patients and is unresponsive to oxygen administration. Physical examination reveals normal to slightly decreased peripheral pulses, a prominent right ventricular impulse without thrills, and usually a soft systolic ejection murmur of Grade I to II along the left upper sternal border. The electrocardiogram may be normal, or it may show signs of right ventricular hypertrophy.

The chest roentgenogram is usually helpful and demonstrates signs of severe pulmonary venous obstruction. The heart size is normal, and the pulmonary vascular markings demonstrate a diffuse reticular pattern and pulmonary edema characteristic of obstruction to pulmonary venous return.

Echocardiography

Echocardiographic findings in atresia of the common pulmonary vein have been reported rarely. One would expect to observe signs of pulmonary hypertension and persistence of the fetal circulatory patterns, including contrast echocardiographic or Doppler evidence of right-to-left shunting at the foramen ovale or ductus arteriosus. In addition, the common pulmonary venous chamber may be visualized behind the left atrium without a connection to the heart or a systemic vein. Total anomalous pulmonary venous connection with obstruction and persistence of the fetal circulation may be difficult to differentiate from this anomaly if the blind common pulmonary venous chamber is not observed.

Cardiac Catheterization

Cardiac catheterization reveals pulmonary hypertension of a severe degree in all cases. Pulmonary angiography demonstrates a large patent ductus arteriosus with predominant right to left shunting and markedly prolonged filling and clearing of the pulmonary vascular bed with contrast material. No opacification of the left atrium is observed and only rarely is the pulmonary venous confluence visualized.[144] Oximetric studies demonstrate equally low oxygen saturations in all chambers of the heart. When there is a step up in oxygenation, this occurs between the superior vena cava and the right atrium and is due to blood returning from the bronchopulmonary collaterals by the azygous system of veins.[145,146]

Management

Early recognition of signs and symptoms of pulmonary venous obstruction is critical if one is to affect the high mortality associated with this cardiac defect. Although cardiac catheterization and angiocardiography have been the diagnostic procedure of choice in previous reports, high-resolution two-dimensional echocardiography with Doppler capabilities may replace this modality in the extremely ill, moribund infant. Aggressive preoperative medical management including early mechanical ventilation and the judicious use of sodium bicarbonate for metabolic acidosis is advocated. In addition, prostaglandin E1 may be helpful if signs of constriction of the ductus arteriosus and poor systemic perfusion are present.

An attempt at surgical correction should be undertaken as soon as the diagnosis is established. Khonsari et al.[142] reported the first infant to survive operation in 1982. Using deep hypothermia and limited bypass supplemented by cold cardioplegic arrest, the ductus arteriosus was first identified and ligated. An anastomosis was performed between the posterior aspect of the left atrium and the common pulmonary venous channel, and the foramen ovale was closed. The postoperative course was uneventful, and the infant was discharged on the seventh postoperative day.

CHAPTER 70

Transposition Physiology

J Timothy Bricker

Transposition physiology is defined as the situation of a systemic and a pulmonary circulation that are connected in parallel rather than in series. Mixing between the systemic and pulmonary circulations is essential for survival. In transposition physiology, the mixing between the parallel circulations is equal to the left-to-right or right-to-left shunt. The right-to-left and left-to-right shunt must be equal in transposition, or the blood volume would end up entirely in the systemic or in the pulmonary circulation.

Oxygenation of the systemic side is reflected in the right-to-left shunt between the two circulations. Thus, the Q_{ES} (effective systemic output) will be equal to the right-to-left shunt. In the same respect, delivery of deoxygenated blood to the pulmonary circulation (Q_{EP}, or effective pulmonary blood flow) is equal to the left-to-right shunt. So, in transposition physiology, it may be seen that mixing is equal to effective pulmonary blood flow, which is equal to effective cardiac output, which is equal to right-to-left shunt, which is equal to left-to-right shunt. This is a fairly simple concept but is regularly a source of confusion for the neophyte performing cardiac catheterization laboratory calculations (see Chapter 54).

Pulmonary blood flow with transposition physiology is unrelated to effective pulmonary blood flow or to oxygenation of the patient. A cyanotic newborn showing normal or increased pulmonary vascular markings on chest radiograph will often be a clue to the neonate with transposition physiology.

CLINICAL SETTING OF TRANSPOSITION PHYSIOLOGY

It must be emphasized that transposition physiology may occur in conjunction with a number of different defects other than the typical d-transposition of the great arteries. Many patients with double outlet right ventricle, single ventricle, and ventricular inversion without transposition (''isolated ventricular inversion'') will have transposition physiology. In the same respect, a patient with classic d-TGA relationship of the great arteries may not have transposition physiology.

One example of this might be a patient with tricuspid atresia and transposition having the physiology of a left-to-right shunt. Another example is that of a patient having a single ventricle with severe pulmonary stenosis, d-TGA relation of the great vessels, and the physiology of a right-to-left shunt. Patients who have ventricular inversion with transposition and without an interatrial or an interventricular communication may have normal physiology—the classic ''congenitally corrected'' transposition.

Although morphologists may argue about the anatomic definitions of transposition, being alert about the physiologic definition of ''transposition physiology'' can help prevent blunders in the catheterization laboratory. We continue to see double outlet right ventricle or isolated ventricular inversion cases with transposition physiology and inadequate mixing who are referred after a cardiac catheterization in which balloon atrial septostomy was omitted because it was not a classical d-TGA. A convenient rule of thumb in the catheterization laboratory is that if a newborn has a higher oxygen saturation in the pulmonary artery than in the aorta, it is either anomalous pulmonary venous return or transposition physiology.

The location of pulmonary venous return should be identified if there is a question of whether the patient has transposition physiology. If transposition physiology is confirmed in a cyanotic

Table 70–1. Indications for Creation of an Atrial Septal Defect in the Catheterization Laboratory

Indication	*Comment*
Transposition physiology	May not be best to perform septostomy if arterial switch is planned for the immediate future and if adequate mixing between the circulations can be assured.
Left atrial hypertension from obstructed egress	An example of this would be a single ventricle with mitral atresia and a restrictive foramen ovale.
Tricuspid atresia with a restrictive atrial septal defect	The effective cardiac output in tricuspid atresia depends upon and is equal to the right-to-left flow at the level of the foramen ovale. Right-sided volume overload (e.g., hepatomegaly) with low cardiac output will be found with a restriction to flow at the atrial level.
Total anomalous pulmonary venous return with obstruction at the atrial level	Extracardiac obstruction of pulmonary venous return is usually recognized but an intracardiac obstruction of anomalous return to the left heart at the atrial septal level is frequently overlooked. Improvement in cardiac output and a decrease in pulmonary edema follow creation of an atrial defect during catheterization in these patients.
Severe right heart failure with pulmonary hypertension	Some pulmonary hypertension patients with intact atrial and ventricular septae have incapacitating symptoms of right heart failure. Creation of an atrial communication will relieve right-sided symptoms at the expense of increased cyanosis.

baby, one should proceed with a balloon septostomy unless an arterial switch is planned for the near future and adequate mixing can be assured in the interim. Transposition physiology is not the only indication for creation of an atrial septal defect (Table 70–1). This concept is a source of occasional confusion when one is attempting to determine whether to perform a septostomy.

ADEQUACY OF MIXING IN TRANSPOSITION PHYSIOLOGY

The mixing between the pulmonary and systemic circulations in transposition physiology may be at the level of the atriae, ventricles, or great arteries. For example, an infant with typical d-TGA and a ventricular septal defect may be well saturated. In general, creation of an atrial defect in such a patient is reasonable because of the possibility of development of a restrictive interventricular communication. Some of these patients may have better mixing and a higher saturation with septostomy and, furthermore, they may improve with a drop in left atrial pressure from septostomy. Mixing at the great vessel level may occur in the patient with transposition physiology and a patent ductus arteriosus. Prostaglandin E_1 therapy to open the ductus arteriosus may serve to improve mixing at the great vessel level. This therapy can be useful for stabilization prior to transport, to cardiac catheterization, and to balloon atrial septostomy.

One of the important problems for the baby with transposition physiology is inadequate mixing. One of the causes of inadequate mixing after septostomy is an inadequate septostomy. An adequate atrial septal defect should be confirmed by angiogram or echocardiogram performed in the catheterization laboratory before the procedure is concluded. Volume loading and an increase in oxygen-carrying capacity by an infusion of packed red blood cells will improve oxygenation in the patient with poor atrial mixing after balloon septostomy. A complicated relationship of the diastolic impedance of the atriae and ventricles is involved in the adequacy of atrial mixing. Anecdotal observations and preliminary clinical studies suggest that the use of prostaglandin E_1 infusions with transposition physiology may increase the problem of poor mixing after balloon atrial septostomy.

Defining poor mixing in transposition physiology is difficult. The apparent increase in poor mixing may be in part due to the increased surveillance with blood gases, transcutaneous oxygen tension measurement, and photometric monitoring of oxygen saturation that is characteristic of current neonatal intensive care practice. Hypoxemia without acidemia in the baby with transposition and an adequate interatrial communication usually gradually improves and is tolerated in the interim. Inadequate mixing with associated acidosis due to hypoxemia is a reason for early repair by Senning, Mustard, or arterial switch technique. Complications of hypoxemia may occur with time in patients with transposition as in patients with right-to-left shunt discussed in Chapter 62. Greater detail about the physiology of transposition, particularly as it relates to the timing and type of surgical intervention, will follow in Chapter 71.

CHAPTER 71

Transposition of the Great Arteries

William H Neches
Sang C Park
Jose A Ettedgui

Transposition of the great arteries, or complete transposition, is a common form of cardiac anomaly and is found in about 5% of all patients with congenital heart disease.[1] The word transposition refers to the discordant ventriculoarterial connection of the great arteries whereby the aorta originates from the morphologic right ventricle and the pulmonary artery originates from the morphologic left ventricle. The consequence of this anatomic arrangement is that nonoxygenated systemic venous blood returning to the heart passes through the right atrium and right ventricle and is ejected into the aorta. Similarly, oxygenated pulmonary venous blood reaches the left side of the heart and is returned to the pulmonary artery.

The clinical situation that results from this cardiac anomaly is characterized by severe and life-threatening hypoxemia early in life. Although Baillie described the first recorded case of transposition of the great arteries almost two centuries ago, in 1797, it remained little more than an anatomic curiosity until the era of cardiac catheterization and cardiac surgery.[2] Prior to this, over 90% of patients with transposition died in infancy and transposition of the great arteries was one of the most common causes of death from congenital heart disease in the first year of life.[3–6]

In recent years, advancements in cardiac catheterization and cardiovascular surgery have transformed the devastating natural history of this anomaly. Blalock and Hanlon developed surgical atrial septectomy in 1950, which resulted in improved survival for infants with transposition.[7] Although the first physiologically corrective atrial baffle procedure was described by Senning toward the end of that decade, the results were unacceptably poor and it was therefore abandoned.[8] A few years later, in 1964, the introduction of another atrial redirection procedure by Mustard revolutionized the approach toward the surgical management of the patient with transposition.[9] The introduction of balloon atrial septostomy by Rashkind and Miller in 1966 was the single most important factor to influence the survival of the infant with transposition.[10] This procedure allowed successful palliation of the young infant with transposition of the great arteries without operation and with low risk. Thus, by the end of the 1960s the availability of balloon atrial septostomy and widespread success with the Mustard procedure resulted in an aggressive approach to the management of the newborn and small infant with transposition of the great arteries.

In recent years, along with the advances in medical and surgical management of patients with this disorder including the arterial switch operation, great strides have also been made in angiocardiography and echocardiography. Although it is now possible to describe precisely the anatomic variations of transposition of the great arteries in a living patient, there is still considerable discussion as to how to describe and classify patients with transposition of the great arteries. Thus, prior to a discussion of the clinical features, diagnosis, or management of patients with this disorder, it seems appropriate to review the anatomic particulars of this abnormality.

ANATOMIC CONSIDERATIONS

Basic Pathologic Anatomy

There appears to be general agreement that transposition of the

great arteries refers to the clinical situation produced by ventriculoarterial discordance in which the aorta and pulmonary artery arise from the wrong ventricles. Unfortunately, in the past, some investigators have described transposition of the great arteries not only as an abnormal ventriculoarterial connection but also in terms of the spatial relationships of the great arteries or on the basis of terminology that has been derived from embryologic hypotheses. These systems have led to confusion in classification and are quite difficult to understand in the presence of the various positioning abnormalities of the cardiac structures within the thorax such as rotational abnormalities, situs inversus, or situs ambiguous. In this chapter, the segmental description of the pathologic anatomy will be employed. For those interested in a more detailed description of the various methods of classification of transposition, references by Van Praagh et al.,[11–13] Van Mierop et al.,[14,15] and Shinebourne et al.[16] can be consulted. This chapter will deal with transposition of the great arteries as a major abnormality itself. Those situations that describe transposition in association with other major intracardiac anomalies such as atrioventricular discordance (corrected transposition), atrioventricular valve atresia, double inlet or single ventricle, or atrial isomerism syndromes are described in other chapters in this book.

The description of the pathologic anatomy of the heart in transposition of the great arteries will characterize the deviations found from various features of the normal heart. It is therefore appropriate to describe these normal characteristics. In the description of the various junctions of the heart, three important features must be distinguished: 1) connections, 2) morphology, and 3) relationships.

Situs solitus is normally present. The right atrium has its various distinguishing characteristics and is connected via a tricuspid valve to a coarsely trabeculated morphologically right ventricle. The tricuspid valve has its usual attachments to the interventricular septum. On the left side of the heart, the smooth-walled, normal-appearing left atrium connects via a mitral valve into a finely trabeculated, morphologically left ventricle, with multiple criss-crossing trabeculations. The left ventricle has a smooth interventricular septal surface with atrioventricular valve attachments away from the septum. There is thus normal intraventricular anatomy and concordant atrioventricular connection. In the heart with transposition these structures have the same characteristics. The conduction system is also normal as are the locations of the sinoatrial and atrioventricular nodes. The distinguishing features lie in the description of the ventriculoarterial junction.

In the normal heart with concordant ventriculoarterial connection, there is a subpulmonary infundibulum. The pulmonary valve is exclusively supported by muscle and there is thus no fibrous continuity between the pulmonary valve and the tricuspid valve. In the normal right ventricle, the muscle tissue that separates these two valves is the crista supraventricularis. On the left side of the heart the aorta is wedged between the mitral valve and the interventricular septum. Unlike the right ventricle, the left ventricle has no muscle tissue separating the mitral valve and the aortic valve. There is fibrous continuity between these two valves and absence of a subaortic infundibulum. Last, the two great vessels normally course in a spiral relationship as they leave the heart. As the pulmonary artery arises from the right ventricle, it ascends in a leftward direction. The pulmonary valve is generally located anterior and to the left of the aortic valve. The aorta arises from the left ventricle in the middle of the heart and ascends toward the right.

Upon external inspection of the heart with transposition of the great arteries, it is immediately apparent that there is an abnormal relationship between the great arteries (Fig. 71–1). The aorta is usually, but not always, anterior and right-sided relative to the pulmonary artery. The arterial trunks ascend in parallel fashion, rather than in a spiral, as is present in the normal heart. The atria and ventricles have their normal external morphologic characteristics and their usual relationships in either the situs solitus or situs inversus positions.

Examination of the ventriculoarterial connection demonstrates the aorta arising from the right ventricle and the pulmonary artery arising from the left ventricle. In the right ventricle there is a muscular infundibulum separating the aortic valve from the tricuspid valve, while on the left, the pulmonary artery arises from the left ventricle and there is fibrous continuity between the leaflets of the pulmonary valve and the mitral valve.

Coronary Arteries

In the normal heart, the coronary arteries arise from the two sinuses of the aortic valve, which face the pulmonary artery. The noncoronary sinus faces posteriorly and somewhat rightward. In transposition, the aorta is positioned anteriorly and generally to the right. The coronary arteries still arise from the two aortic valve sinuses that face the pulmonary artery.[17] The noncoronary sinus generally faces anteriorly and to the right. There are many variations of aortic position in hearts with ventriculoarterial discordance. However, regardless of the position of the aorta in relationship to the pulmonary artery the coronary arteries consistently arise from one or both of the aortic valve sinuses that face the pulmonary artery. This results in a relatively small distance between the origin of the coronary arteries on the aorta and the wall of vessels and the pulmonary artery, and this should facilitate

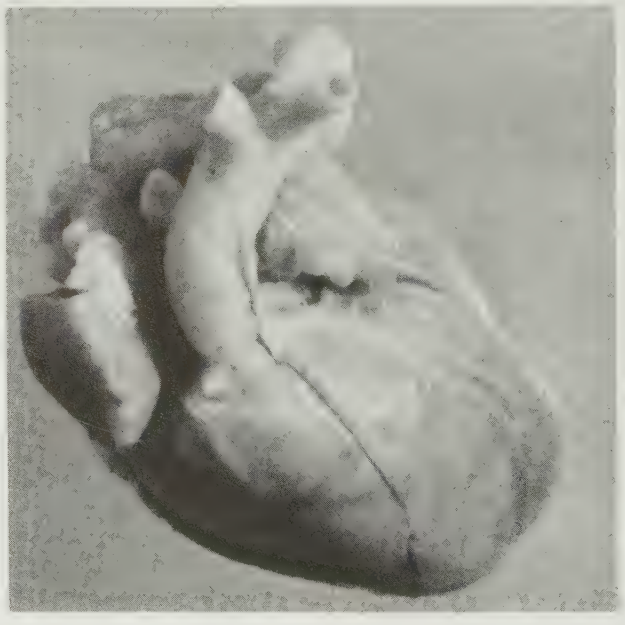

Fig. 71–1. The external appearance of a heart with transposition of the great arteries.

transplantation of the coronaries from the aorta to the pulmonary artery if an arterial switch procedure is performed.

The sinus node artery is of considerable importance in transposition of the great arteries.[18,19] This vessel arises from the right coronary artery and generally runs in the anterior interatrial groove. If it courses within the atrial myocardium, this exposes it to damage during a Blalock-Hanlon atrial septectomy or at open-heart surgery when the surgeon excises the interatrial septum while performing a Mustard procedure. The sinus node artery may also course inside the wall of the right atrial appendage until it reaches the sinoatrial node. In other cases, the sinus node artery may arise from the circumflex coronary artery especially when the circumflex runs behind the pulmonary artery. When the sinus node artery passes across the lateral aspect of the right atrium it is at risk during an atriotomy.

Major Complicating Lesions

Ventricular Septal Defect

As in the heart with normal ventriculoarterial connection, ventricular septal defects may be of varying sizes and may occur in any position in the interventricular septum (Fig. 71–2). The typical defect in transposition of the great arteries occurs in the outlet septum and may be entirely muscular or extend into the membranous septum as well.[20] In these hearts, there is most often a malalignment of the outlet septum that is deviated rightward relative to the remainder of the ventricular septum.[21] As a result, the pulmonary valve and pulmonary artery may override the ventricular septum in varying degree. This overriding leads to a spectrum of cardiac malformations that range between discordant ventriculoarterial connections with slight override of the pulmonary artery, to the Taussig-Bing malformation (double outlet right ventricle with subpulmonary ventricular septal defect). This latter anomaly, though anatomically part of the complex of double outlet right ventricle, physiologically is in the category with transposition. Although the pulmonary artery arises from the right ventricle along with the aorta, the subpulmonic location of the ventricular septal defect results in highly oxygenated pulmonary venous blood passing into the pulmonary artery just as it does in transposition. In some cases with transposition and ventricular septal defect or in the Taussig-Bing malformation, significant deviation of the outlet septum into the right ventricular outflow tract may result in subaortic outflow obstruction.[22,23] This may result in reduced flow into the aorta during fetal life and may be the cause for the high incidence of coarctation of the aorta that is found in conjunction with this anomaly.[24] Other types of ventricular septal defects such as those located in the membranous septum or muscular trabecular defects (single or multiple) may be present in patients with transposition of the great arteries.[20]

The major difference between these defects in transposition as compared to the heart with concordant ventriculoarterial connection lies in the surgical approach. If an atrial baffle procedure is performed, the right ventricle remains the systemic ventricle after repair. Thus, a ventricular septal defect must be approached via the right atrium and tricuspid valve rather than through a ventriculotomy.[25,26] In general, this is not a problem with defects in the membranous septum or with isolated muscular trabecular defects. On the other hand, multiple muscular defects are more difficult to repair since direct vision is more limited without the availability

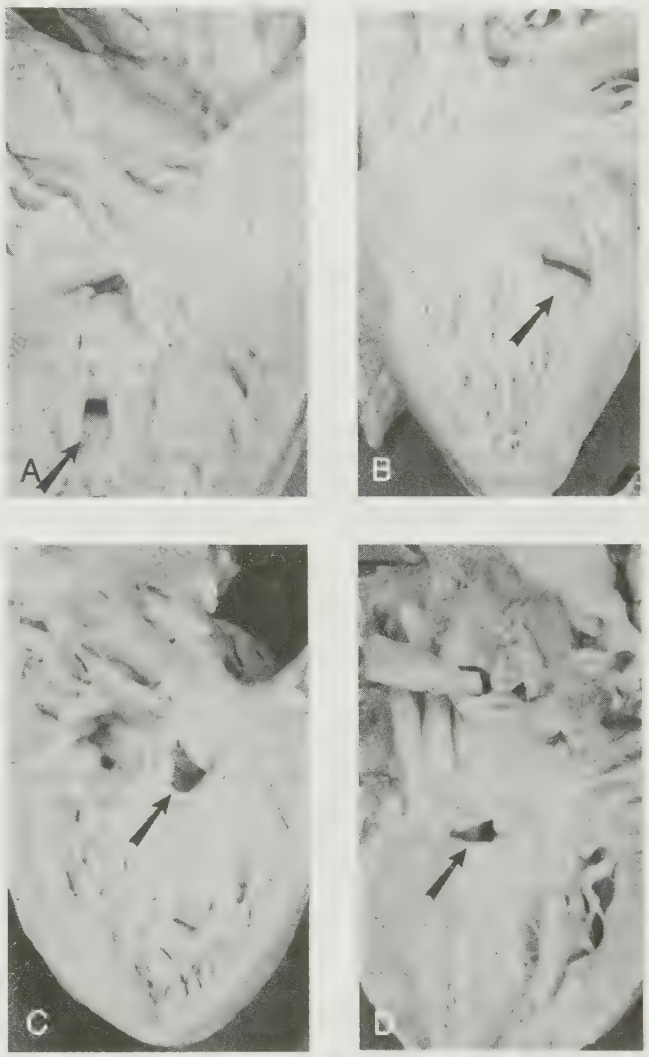

Fig. 71–2. Ventricular septal defects in transposition of the great arteries (arrows). (A) Inlet defect, left ventricular aspect. (B) Inlet defect, right ventricular aspect. (C) Malalignment defect, right ventricular aspect. (D) Malalignment defect, left ventricular aspect.

of a ventriculotomy. Fortunately, these latter defects are much less common in association with transposition. Inlet ventricular septal defects are of major importance in patients with transposition of the great arteries. These may be purely muscular or may be membranous with muscular extension.[20] The major significance of these defects in patients with transposition is due to the fact that they lie underneath the septal leaflet of the tricuspid valve. Again, if an atrial baffle repair is contemplated, surgical access must be via the right atrium rather than through a ventriculotomy. The tricuspid valve overlies the defect and must be retracted in order to perform the repair adequately. It is possible that injury to the valve during repair may be responsible for the tricuspid regurgitation seen in some patients who have undergone closure of inlet ventricular septal defects at the time of an atrial baffle operation.

In most hearts with transposition and ventricular septal defect, the conduction tissue is also located in its usual position.[27,28] With the more common type of membranous or muscular outlet defects the conduction tissue lies on the left ventricular side of the septum

and courses around the posterior and caudal margins of the defect. In contrast, when a purely muscular inlet defect is present, it is likely that the conduction tissue will run in the muscular ridge between the cephalad rim of the defect and the membranous septum.[29] When this type of defect is present, the surgeon must take great care when placing sutures in the cephalad portion of the defect rather than caudally as is usually the case.

Pulmonary Stenosis

Left ventricular outflow tract obstruction can be demonstrated in over 30% of patients with transposition of the great arteries.[30–32] In patients with an intact interventricular septum, a dynamic form of left ventricular outflow tract obstruction is most common. As a result of the pressure difference between the systemic right ventricle and subpulmonary left ventricle, there is usually a distinct leftward bulge in the upper portion of the interventricular septum into the left ventricular outflow tract. This dynamic obstruction occurs during systole and is readily appreciated both angiographically and by echocardiography.[33,34] In many cases this results in a relatively small (20 to 30 mm Hg) peak systolic pressure gradient between the left ventricle and pulmonary artery. In some cases, especially those with greater left ventricular outflow tract gradients, a discrete fibromuscular shelf may be present on the septal surface of the outflow tract and may even extend laterally onto the mitral valve.[31] This shelf most commonly represents a hemodynamic change in the septal surface secondary to the obstruction resulting from the protrusion of the interventricular septum into the left ventricular outflow tract. Valvar pulmonary stenosis is a possible but infrequent cause of left ventricular outflow obstruction.[30,35] If present, it is usually in association with the dynamic form of obstruction and oftentimes is the less severe of the two. Other forms of subpulmonic obstruction include anomalous attachments of atrioventricular valve tension apparatus and fibrous tissue tags.[35]

An important form of subpulmonic obstruction in transposition of the great arteries is the form that occurs in the presence of a ventricular septal defect. These hearts have a more extensive type of stenosis consisting of a narrow fibromuscular tunnel in the left ventricular outflow tract.[36] In the discussion regarding ventricular septal defect, the form of transposition of the great arteries and ventricular septal defect was described in which the pulmonary valve overrides the interventricular septum. In some of these cases the outlet septum is sufficiently deviated into the right ventricle so as to produce right ventricular outflow tract obstruction (subaortic stenosis). On the other hand, when transposition of the great arteries with ventricular septal defect has accompanying subpulmonic stenosis, the outlet septum is deviated leftwards and actually has come through the ventricular septal defect. The outlet septum is attached to the anterolateral muscle bundle of the left ventricle thus producing obstruction to the subpulmonic outflow tract, and some degree of override of the aortic valve over the ventricular septum. In these cases there also may be an extension of a fibrous shelf from the underside of the outlet septum across the outflow tract and onto the surface of the mitral valve. This shelf may worsen the stenosis produced by the deviation of the outlet septum or itself produce stenosis. In patients with transposition of the great arteries and ventricular septal defect, as in patients with an intact interventricular septum, subpulmonic stenosis can also be produced by anomalous attachments of atrioventricular valve tension apparatus or fibrous tissue tags. In addition, in the presence of a ventricular septal defect, an aneurysm of the membranous septum may be present and cause subpulmonic stenosis. In reality this is usually a pouch of tricuspid valve tissue that prolapses during systole through the ventricular septal defect and into the left ventricular outflow tract.[35,37] In some cases a redundant portion of the mitral valve, rather than tricuspid valve tissue, may be responsible for this systolic bulge. In either case, it is important to recognize that these structures represent atrioventricular valve tissue since wide excision at the time of repair may result in postoperative atrioventricular valve regurgitation.

Other Complicating Lesions

Patent Ductus Arteriosus

This structure is usually present in all newborns with transposition and most often closes spontaneously in the first few days of life. In patients with transposition and an intact interventricular septum, closure of the ductus arteriosus results in profound hypoxemia and is usually the event that precipitates referral of the patient for evaluation. Although patency of the ductus arteriosus is important in the early management of the patient with transposition as can be readily demonstrated by the administration of prostaglandin E_1, persistent patency of the ductus arteriosus can be a difficult management problem.[38] A large persistent ductus arteriosus may lead to congestive heart failure and put the patient at risk for developing pulmonary vascular disease.

Coarctation of the Aorta

This lesion is present in about 5% of patients with transposition of the great arteries.[24] It is more commonly associated with ventricular septal defect but on occasion may be present when there is an intact interventricular septum. Interruption of the aortic arch is a rare, though well-recognized, association with transposition of the great arteries.[5]

Other Cardiac Anomalies

In addition to those anomalies mentioned above, other anomalies that are infrequently present in association with transposition of the great arteries include some aortic arch anomalies, various types of partial or total anomalous pulmonary venous drainage, systemic venous drainage anomalies, and cor triatriatum.[5]

ANATOMIC CLASSIFICATION

In the past, the main distinguishing features of the ventriculoarterial junction (the connection, the relationships and the infundibular morphology) have been used individually or collectively to describe transposition of the great arteries.[11,12,14] This has led to controversy as to whose definition of transposition is more correct.[13,15] In addition, if one considers great vessel relationships or infundibular morphology in the definition of transposition, then exceptions immediately must be put forth in order to explain the variations from the rules.[12] The discordant ventriculoarterial connection is the only distinguishing characteristic that is the hallmark of transposition of the great arteries and always produces the clinical picture that we recognize as transposition.

Relationships

The relationship of the great arteries is variable within the chamber combinations that produce the clinical picture of transposition

of the great arteries. In 60% of the patients, the aorta is anterior and to the right of the pulmonary artery. The classification of Van Praagh, which describes transposition on the basis of relative great artery position and thus their "D" or "L" relationship, would term this to be "D transposition."[11] There are problems with this classification. The aorta may be anterior to the pulmonary artery but may also be located to its left. The Van Praagh classification will need to use a different term ("L transposition") to describe this anatomy. In addition, if a rotational anomaly is present, a heart may actually have the pulmonary artery anterior and spiraling around the aorta, as is seen in a normal great artery relationship, despite the presence of ventriculoarterial discordance.[12] In situs inversus with mirror image arrangement, the Van Praagh classification scheme will classify atrioventricular concordance and ventriculoarterial discordance separately as "L-loop of the ventricles and L-transposition." It is clearly more difficult and confusing to use this method to describe the various types of anatomic variations of ventriculoarterial discordance that produce the clinical picture of transposition of the great arteries.

Infundibular Morphology

In the majority of hearts with transposition of the great arteries, there is a subaortic infundibulum and fibrous continuity between the mitral valve and the pulmonary valve. However, in hearts with a ventricular septal defect, there may be a muscle ridge that forms a wedge of tissue that separates the attachment of the mitral valve from the attachment of the pulmonary valve. In addition, a muscle ridge from the interventricular septum may also be present that almost forms an infundibulum where it merges with the parietal muscle bar. In a minority of hearts with transposition of the great arteries, there may actually be a large subpulmonary muscular infundibulum. Usually, this muscle structure is nothing more than the inner curvature of the heart (the inner lining of the transverse sinus between the posterior aspect of the pulmonary artery and the anterior aspect of the atrium). In general this structure is attenuated to permit fibrous continuity between the mitral valve and the pulmonary valve, but this is not always true. Thus, if one defines transposition of the great arteries on the basis of absence of a subpulmonary infundibulum, then all of these hearts without fibrous mitral-pulmonary valve continuity would not fit into this classification. However, the presence of a subpulmonary muscular structure in each of these situations does not alter the circulatory pathway nor does it even alter the surgical approach. Thus, these hearts with discordant ventriculoarterial connections and with a subpulmonary muscular structure and fibrous discontinuity between the mitral and pulmonary valves are still appropriately classified as having transposition.

As can be seen from the above brief discussion, "typical" great artery relationships and infundibular morphology are commonly present in the heart with transposition. Because differences can occur, however, it is not possible to make the diagnosis of transposition based on these features alone.

For the clinician, the fine points of anatomic detail that may separate the various types of transposition and different classifications are more of academic interest. In general, it is the presence or absence of associated cardiac anomalies that dictate the presentation, clinical course, and eventual surgical approach to the management of these patients. With this in mind the subsequent discussion in this chapter will focus on three main broad categories of patients with transposition of the great arteries.

1. Transposition with intact interventricular septum (complete transposition)—the heart with atrioventricular concordance and ventriculoarterial discordance regardless of atrial situs or heart position. These may or may not have left ventricular outflow tract obstruction.
2. Transposition with ventricular septal defect—hearts with complete transposition and an interventricular communication that do not have narrowing in the left ventricular outflow tract.
3. Complex transposition—these include hearts with complete transposition, ventricular septal defect, and varying degrees of left ventricular outflow tract obstruction. These are usually characterized by significant subpulmonic stenosis and equal right and left ventricular pressures. Included in this category are some patients with pulmonary atresia. Some cases have varying degrees of hypoplasia of the right ventricle.

This anatomic arrangement in transposition of the great arteries, concordant atrioventricular connection with discordant ventriculoarterial connection, is present in both situs solitus and situs inversus. This same clinical picture is produced by a discordant atrioventricular connection with concordant (normal) ventriculoarterial connection. In this lesion, termed "isolated ventricular inversion," the systemic venous blood passes from the right atrium into a morphologically left ventricle, which is connected to an aorta. Pulmonary venous blood is pumped into the lungs by a morphologic right ventricle connected to the left atrium and pulmonary artery. The internal cardiac anatomy is what would be expected for the respective ventricles and their connections. This lesion is discussed further in Chapter 73 on Ventricular Inversion.

EMBRYOLOGY

There are a number of different theories to explain the embryologic origin of transposition of the great arteries. Since substantial controversy still exists regarding the definition and classification of transposition, it is not surprising that a similar debate continues regarding the hypotheses of embryologic development. Fortunately, the intracardiac structures in hearts with transposition of the great arteries generally have developed normally. Thus, the controversy is centered around hypotheses that explain the abnormality of conotruncal development. Only a brief summary of the embryology of transposition will be presented here. A detailed description of normal morphogenesis can be found in Chapter 2 in this text while a number of excellent references provide a detailed overview of the embrylogic hypotheses (Anderson et al., 1974[39,40]; de la Cruz et al., 1974[41] and 1981[42]; Goor et al., 1972[43]; Shaher 1973[5]; and Van Mierop et al., 1963[44]).

A number of events take place during embryonic cardiac development that result in normal connection and relationship of the great arteries. These include shifting of the bulbus cordis or conus region to the midline, twisting of the conus region, and septation of the great arteries. In 1909 Keith[45] proposed the differential conal absorption hypothesis to explain the production of transposition of the great arteries. This has undergone a number of modifications so that the current theories include both abnormal canal growth and absorption leading to discordant ventriculoarterial connec-

tions.[42] In normal embryologic development, a bilateral conus develops beneath the aorta and the pulmonary artery. At that stage the developing aortic valve is to the right and the pulmonary valve to the left. According to this theory, there is further development of the subpulmonary conus and absorption of the subaortic conus. This differential of growth and absorption results in the pulmonary valve being elevated and pushed anteriorly, thus coming to lie over the right ventricular outflow tract; while the aortic valve descends posteriorly and rightward thus coming to rest over the left ventricular outflow tract. In transposition of the great arteries, the reverse occurs. The subaortic conus continues to develop and the subpulmonary conus is absorbed. The aorta then is moved superiorly and anteriorly and remains to the right. The absorption of the subpulmonary conus results in the pulmonary valve migrating inferiorly, posteriorly, and remaining to the left.

Another hypothesis was that transposition of the great arteries occurred as a result of abnormal formation of the aortopulmonary septum.[44] This septum normally develops in spiral fashion to separate the truncus arteriosus and it was theorized that abnormal fusion of the truncal ridges resulted in septation of the truncus arteriosus in a straight fashion thus producing an anterior aorta and posterior pulmonary artery.

Unfortunately neither of these theories is able to explain completely all of the various anatomic and positional abnormalities that occur in hearts with ventriculoarterial discordance. Although each provides a seemingly valid explanation for the more common forms of transposition, it is necessary to combine both of these hypotheses to explain the more unusual forms.[42] In addition, current research in experimental embryology continues to provide new and interesting information regarding cardiac morphogenesis. It has recently been demonstrated that a specific region of neural crest tissue contributes cells to the developing truncal septal region and outflow tract of the heart and that damage to this area results in conotruncal abnormalities.[46] However, since a specific embryologic model of transposition of the great arteries still does not exist, these embryologic hypotheses still remain to be validated in the future.

EPIDEMIOLOGY AND GENETICS

The incidence of transposition of the great arteries is approximately 5% of infants born with congenital heart disease. The incidence reported in any study is dependent upon the nature of the series and what group of patients with transposition were included or excluded from the numerator. In 1973, Campbell[4] summarized seven series describing the incidence of different cardiac malformations at birth. The overall incidence of transposition of the great arteries was 4.2% with a range in each series from 2.5 to 11%. Hoffman and Christianson[1] evaluated congenital heart disease in a cohort of 19,502 births. They reported a 3.7% incidence of transposition of the great arteries. When their data were combined with the data from six other series, transposition was found in 4.7% of over 3000 infants with congenital heart disease. The incidence reported in these other studies ranged from a low of 2.6% to a high of 7.8%. In the largest prospective survey, Mitchell, et al.[47] found the incidence of transposition to be 2.6% of live births with congenital heart disease in a cohort of over 56,000 total births. Thus, the actual incidence of transposition of the great arteries is difficult to determine exactly.

The etiology of transposition of the great arteries remains obscure. Despite the ever increasing range of reported hereditary syndromes, chromosomal abnormalities or other congenital malformations, transposition of the great arteries is rarely associated with these syndromes. In addition, extracardiac malformations are relatively infrequent (less than 7%) and are generally minor in patients with transposition.[48] In general, transposition of the great arteries appears to occur sporadically and is not familial. However, it has been found to occur in greater frequency in siblings of patients with transposition than would be expected to occur on the basis of its frequency in the general population.[49,50] This suggests a multifactorial inheritance resulting from genetic-environmental interaction with the environmental factor playing a major role.[50] Of note is the fact that transposition was not reported to have occurred in the offspring of a large group of mothers with congenital cardiac anomalies.[51] However, very few of these mothers had transposition of the great arteries themselves and it remains to be seen what the outcome of pregnancies in mothers with transposition will be as they reach child-bearing age. In view of the absence of a familial incidence or genetic inheritance patterns for transposition of the great arteries, the fact that the male-to-female ratio is approximately 2:1 in most series is surprising and needs to be explained. Despite this sex difference, there does not appear to be a racial predilection[52] or any other epidemiologic factor. No specific etiologic agent has been identified. However, transposition is seen more frequently than expected in infants of diabetic mothers.[3,53] Nora and Nora[50] suggested that in addition to diabetes, other potential environmental teratogenic agents may have a role in producing transposition. These include amphetamines, trimethadione, and sex hormones.

PHYSIOLOGY AND HEMODYNAMICS

In the normal heart, the circulation is connected in series. The systemic venous return passes into the pulmonary artery while the pulmonary venous return passes into the systemic arterial circulation. In the heart with transposition of the great arteries, the aorta arises from the right ventricle and the pulmonary artery from the left ventricle. Since the atrioventricular connections are normal, the result of this abnormal arterial connection is that the circulation is no longer in series. Instead, there are now two separate parallel circulations (Fig. 71–3). The systemic venous return passes through the right heart and is ejected into the aorta, while the pulmonary venous return passes through the left heart and is again ejected into the pulmonary artery. This physiologic arrangement is incompatible with life unless some means exists for mixing of blood between the two circulations (Fig. 71–4). In the neonate with transposition of the great arteries and an intact interventricular septum, a foramen ovale or atrial septal defect is usually present and facilitates bidirectional exchange of blood at the atrial level. In addition, the presence of a patent ductus arteriosus enhances this exchange, allowing for blood to pass from aorta to pulmonary artery at the level of the ductus and pass in the opposite direction from the left side of the heart to the right side of the heart at the atrial level. If there is no intra-atrial communication, this exchange must occur at ventricular level, during diastole, in a similar direction. In the absence of an intracardiac communication, the patient will not survive since bidirectional shunting usually does not occur at ductal level. Unfortunately the ductus arteriosus is

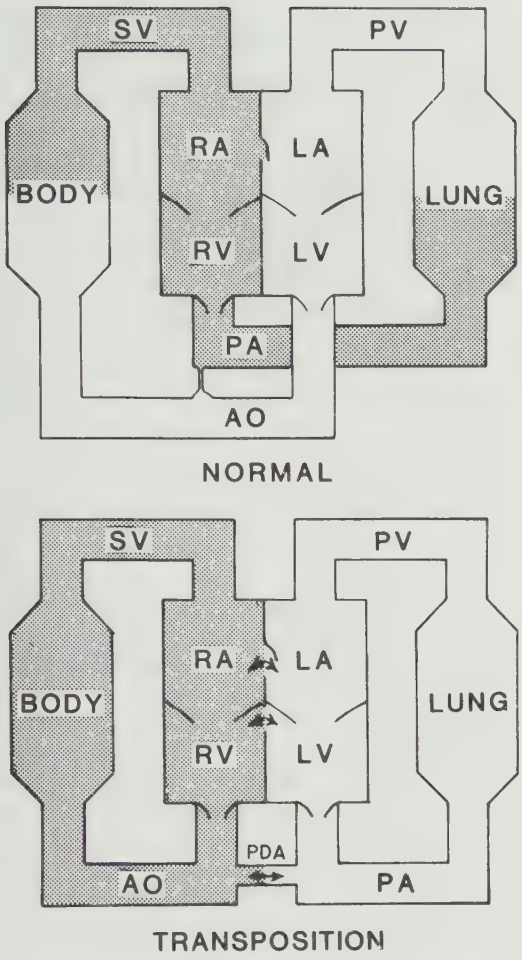

Fig. 71–3. Diagram of the circulatory pathways in transposition of the great arteries. AO = aorta, PV = pulmonary veins, LA = left atrium, RA = right atrium, LV = left ventricle, RV = right ventricle, PA = pulmonary artery, SV = systemic veins, PDA = patent ductus arteriosus.

usually a transient neonatal structure and tends to close physiologically within a few days after birth. The closure of the ductus is the event that precipitates a dramatic change in the clinical appearance of the patient from an apparently healthy newborn to one with intense cyanosis. The importance of the ductus arteriosus in providing a route for this interchange between the two circulations is graphically demonstrated on a continuing basis to clinicians who care for these patients. Prior to balloon atrial septostomy and sometimes even afterwards, the administration of prostaglandin E_1 to maintain patency of the ductus arteriosus usually results in a dramatic improvement in the patient's arterial oxygen saturation. However, if an adequate intra-atrial communication is not present, pulmonary venous congestion may result. Conversely, if this drug is withdrawn prior to the creation of an adequate interatrial communication, the patient will usually develop intense cyanosis within a short period of time.

The patient with transposition of the great arteries and a significant sized ventricular septal defect presents an entirely different clinical picture. These patients often have adequate exchange of blood with a combination of mixing at atrial and ventricular levels.

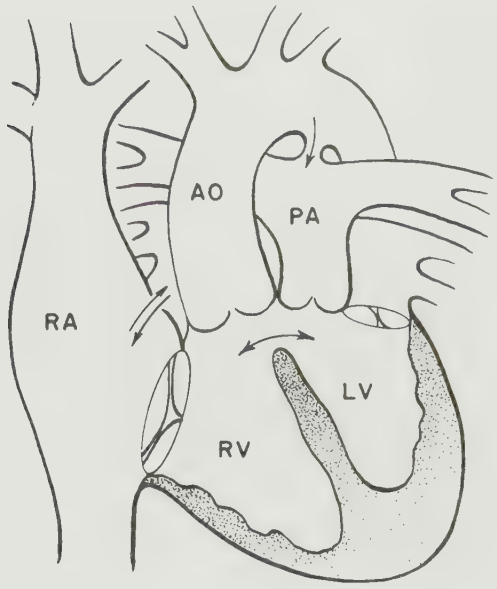

Fig. 71–4. Diagram of a heart with transposition of the great arteries indicating the possible sites of mixing of blood between the systemic and pulmonary circulations (arrows). See Fig. 71–3 for legend to abbreviations.

Shunting is generally bidirectional although it is predominantly from right ventricle to left at ventricular level and from left to right at atrial level. As a result of the adequacy of blood exchange at atrial and ventricular levels, these patients are only mildly cyanotic in the early neonatal period and therefore the presence of a significant cardiovascular anomaly may not be suspected until a few weeks later.

The behavior of the muscular arterioles of the pulmonary vascular bed in infants with transposition of the great arteries is similar to that in patients with other anomalies.[54] Despite the large amount of pulmonary blood flow in patients with transposition of the great arteries and an intact interventricular septum, pulmonary vascular resistance begins to fall within a few days after birth. This facilitates the flow of blood from the aorta into the pulmonary artery as long as the ductus arteriosus remains open. In the presence of a ventricular septal defect, the initial drop in pulmonary vascular resistance at a few days of age promotes increased shunting at the ventricular level. This increase in pulmonary blood flow results in a prompt increase in the tone of the muscular pulmonary arterioles. As a result of this renewal of arteriolar tone, the degree of shunting at ventricular level is again reduced and thus the signs and symptoms of congestive heart failure are temporarily averted. Thus, in transposition with a large ventricular septal defect, the pulmonary and systemic vascular resistances remain relatively balanced for a period of about 3 to 6 weeks. As occurs in other congenital cardiac anomalies that are associated with shunting at ventricular level and significantly increased pulmonary blood flow, the pulmonary arterioles gradually lose their muscular tone by about 3 to 6 weeks of age. This results in the appearance of the clinical symptoms of congestive heart failure toward the end of the first month of life.

The physiology in patients with complex transposition (transposition of the great arteries, ventricular septal defect, and pul-

monary stenosis) differs from either of the other two clinical forms. In patients with transposition and an intact interventricular septum, symptoms appear in early life and are due to poor mixing of the separate parallel circulations. In transposition and ventricular septal defect, cyanosis is not the major problem. These patients present with congestive heart failure toward the end of the first month of life as a result of extremely large pulmonary blood flow. In patients with complex transposition there is a large ventricular septal defect and the balance between pulmonary and systemic blood flow is dependent upon the degree of pulmonary stenosis. Thus, these patients have a physiologic situation similar to patients with tetralogy of Fallot. In the presence of severe pulmonary stenosis or pulmonary atresia, these patients present with cyanosis and reduced pulmonary blood flow in the early days of life. On the other hand, if the degree of pulmonary stenosis is less severe, then clinical presentation is due to the presence of cyanosis and/or the detection of a heart murmur and may occur even later in infancy.

The neonate with transposition of the great arteries and an intact interventricular septum usually has a significant degree of hypoxemia with systemic arterial Po_2 in the low 30s and often even less than that. This low level of arterial oxygenation is surprisingly well tolerated by many neonates with transposition. It is likely that the polycythemia normally present in the neonate results in the ability for adequate oxygen delivery to the tissues. Thus, these infants often have a normal pH or a relatively mild degree of compensated metabolic acidosis in the first few days of life.

CLINICAL FEATURES

Cyanosis of the mucous membranes and nailbeds is an almost universal clinical feature of the infant with transposition of the great arteries and an intact interventricular septum. However, the intensity of this cyanosis can be modified by the presence of associated abnormalities. Thus, the presence of a patent ductus arteriosus and an adequate interatrial communication in the neonate may sufficiently facilitate mixing so as to make cyanosis not apparent at rest. A large ventricular septal defect may have a similar effect and may even provide adequate enough mixing so that the infant may not appear cyanotic even with exercise such as crying or feeding. Similarly, in patients with complex transposition (ventricular septal defect and pulmonic stenosis) the degree of pulmonic stenosis may be sufficient to provide just the right balance between pulmonary and systemic blood flow. Thus, the patient with complex transposition may be cyanotic or mildly cyanotic at rest but usually will have significant cyanosis at the time of exercise.

The right ventricle is the systemic ventricle in the patient with transposition of the great arteries. Thus, a prominent parasternal impulse indicating hyperdynamic motion and hypertrophy of the underlying right ventricle is usually appreciated on palpation of the precordial area. As a result of the usual anatomic relationship with the aorta being anterior to the pulmonary artery, the loud high velocity closure of the aortic valve is usually magnified. Thus, the second heart sound is often palpable in the patient with transposition.

On auscultation the second heart sound is usually single. This results from the loud closure sound of the anterior aorta and the fact that the soft closure sound of the pulmonic valve is difficult to appreciate due to its posterior location within the chest. However, in some patients with transposition it may be possible to hear splitting of the second heart sound. In the neonate and infant with transposition of the great arteries and an intact interventricular septum there is usually no murmur present on auscultation. This may also be true in the older child with this anatomy. However, since there is often some degree of dynamic left ventricular outflow tract obstruction in most patients with transposition past the period of infancy, it is common to find a soft grade I or II/VI systolic ejection murmur present at the mid to upper left sternal border. It is important to note that although this systolic ejection murmur is commonly present, the absence of a murmur in a patient with transposition and intact interventricular septum does not preclude the presence of substantial left ventricular outflow tract obstruction. We have seen a few patients with left ventricular pressure at systemic level and a left ventricular outflow tract gradient of 70 or 80 mm Hg who had no murmur on auscultation.

When there is a ventricular septal defect, a plateau pansystolic murmur is usually present at the lower left sternal border. As in the normal heart, there is an inverse relationship between the size of the ventricular septal defect and the intensity of the murmur with louder murmurs usually produced by smaller defects. It is interesting to note that despite the presence of increased pulmonary blood flow in patients with transposition and an intact interventricular septum or a ventricular septal defect it is unusual to hear the diastolic murmur that one associates with increased flow across the mitral valve in the heart with normally related great arteries.

Patients with complex transposition have a physiologic situation similar to the patient with tetralogy of Fallot. As a general rule in these patients, there is an ejection murmur along the upper left sternal border. The intensity of this murmur, as in the patient with tetralogy, has an inverse relationship to the degree of subpulmonic outflow obstruction. Patients with a moderate degree of obstruction have a prominent murmur while those with more severe degrees of obstruction usually have a soft murmur.

NONINVASIVE STUDIES

Electrocardiogram

Right axis deviation and right ventricular hypertrophy are present on the electrocardiogram in the patient with transposition of the great arteries. Since this is the normal pattern seen in the newborn it is not possible to suspect the presence of transposition on the basis of this finding on electrocardiogram (nor to differentiate it from any other type of congenital heart disease that may show a similar pattern in the neonate). In the patient with transposition, this pattern persists as long as the right ventricle remains the systemic ventricle. Thus, the patient who has undergone an atrial baffle repair, such as a Mustard or Senning operation, will continue to have electrocardiographic signs of right ventricular hypertrophy throughout life. In children with an associated ventricular septal defect and/or pulmonic stenosis, the presence of a hypertrophied left ventricle may alter the usual dominance of the right ventricle and result in the pattern of biventricular hypertrophy. Hypoplasia of the right ventricle should be suspected when right ventricular hypertrophy is absent in a patient with transposition and a ventricular septal defect. It is also important to note that on occasion, the usual right ventricular hypertrophy may not be found

in the patient with transposition of the great arteries even with an intact interventricular septum. Although this is uncommon in the patient with transposition, the absence of right ventricular hypertrophy on electrocardiogram cannot be construed as an indication that transposition is not present.

Right atrial enlargement, as evidenced by narrow peaked P waves of greater than 2.5 mm in height, is occasionally found on the electrocardiogram of a patient with transposition. Left atrial enlargement is generally not seen despite the large volume of blood that is handled by the left atrium in patients with this abnormality. Arrhythmias are uncommon in the unoperated patient with transposition. However, following atrial baffle procedures, patients are often found to have atrioventricular dissociation with junctional rhythm. Various types of atrial bradyarrythmias and tachyarrhythmias, indicating the presence of sick sinus syndrome, are commonly found a number of years postoperatively in patients who have undergone atrial baffle repair. These problems will be discussed in more detail in the section dealing with surgical followup later in this chapter.

Radiography

In general, the neonate with transposition of the great arteries has a normal chest roentgenogram. In about one-third of infants with transposition and an intact interventricular septum, what has been described as a "classic" transposition chest roentgenogram is seen (Fig. 71–5). In these patients the mediastinal shadow is narrow, probably due to the anteroposterior relationship of the great arteries that is often found in this anomaly. The heart is somewhat ovoid and the resulting image is what has been described as an "egg on a string." Although this has been the classically described radiographic pattern, it can be seen in normal patients with a small or absent thymus, or in patients with other congenital cardiac anomalies. In addition, the absence of this radiographic pattern by no means precludes the presence of transposition of the great arteries.

After the first few days of life, the patient with transposition and an intact interventricular septum has increased pulmonary blood flow and will usually have increased pulmonary vascular markings radiographically. Cardiomegaly is generally not seen. However, it may be found if congestive heart failure is present and balloon atrial septostomy as yet has not been performed. Patients with other forms of transposition will exhibit the radiographic pattern that would be expected on the basis of their associated anomalies. Thus, patients with an associated ventricular septal defect will usually have cardiomegaly and increased pulmonary vascular markings. If severe congestive heart failure is present, a pulmonary venous pattern may also be found radiographically. In the patient with complex transposition the heart size is usually normal and the pulmonary vascular markings are normal; if severe pulmonary stenosis or pulmonary atresia is present, the pulmonary vascular markings are decreased.

There are some important features of the pulmonary vascular markings in the patient with transposition that need to be stressed. In the patient with transposition and an intact interventricular septum, there may be a discrepancy between the blood flow to the right and left pulmonary arteries.[55] In many cases, approximately two-thirds of the output of the left ventricle may be directed preferentially to the right lung. This may result in a greater increase in the pulmonary vascular markings of the right lung as compared to the left.

Echocardiography

In the past, cyanotic infants required urgent cardiac catheterization to establish an anatomic diagnosis and plan the approach to management. With the advent of M-mode echocardiography, a variety of findings were described in association with transposition. Although the simultaneous visualization of both great arteries reflects their anteroposterior relationship in transposition,[56] this relationship can also be found in children with other forms of congenital heart disease, as well as in normal infants.[57] The determination of systolic time intervals in the patient with transposition reveals that the posterior great vessel (usually the pulmonary artery) opens before and closes after the anterior aorta.[58]

Fig. 71–5. Chest roentgenogram in transposition of the great arteries (see text).

However, this does not always hold true especially when there is an increase in the left ventricular afterload. Imaging of both great vessels from the suprasternal notch position together with a peripheral injection of echocardiographic contrast material has also been employed. From this angle, the aorta is almost always anterior to the pulmonary artery.[59] Although early opacification of the anterior vessel occurs in transposition, it is also found with other anomalies and in the presence of significant bidirectional shunting. Thus, although the diagnosis of transposition of the great arteries may be suspected, it cannot be made reliably on the basis of M-mode echocardiography alone, since false positive or equivocal findings are often present.

Two-dimensional echocardiography has had a dramatic impact on the noninvasive diagnosis of transposition of the great arteries. With this technique it is now possible reliably to demonstrate the atrioventricular and ventriculoarterial connections. Cross-sectional images obtained from different views will demonstrate that the aorta arises from a morphologic right ventricle that receives the systemic venous return and the pulmonary artery arises from a morphologic left ventricle.[60] Thus, it is possible to demonstrate the presence of the physiologic and anatomic abnormalities that give rise to the clinical picture of transposition of the great arteries regardless of the position of the heart within the chest or the relationship of the great arteries. All of the echocardiographic modalities, two-dimensional, M-mode, and Doppler echocardiography, are important in demonstrating the associated lesions and physiologic derangements that can occur in the patient with transposition.

While performing the echocardiographic scan, it is advisable to follow a systematic sequential approach in order to delineate the presence or absence of certain abnormalities at each specific step. This reduces the possibility of overlooking any abnormalities. It is important to determine the situs in each patient, and this should be done from the subcostal position at the beginning of each study. In situs solitus, a short axis view of the abdominal vessels at the level of the diaphragm shows the inferior vena cava to the right of the spine and the aorta to the left. Clockwise rotation of the transducer to obtain a longitudinal view allows tracing of the inferior vena cava to the right-sided atrium. In situs inversus, the aorta lies to the right of the spine. The inferior vena cava is on the left side and drains to the left-sided atrium.[61]

In the patient with situs solitus, the parasternal long axis view will demonstrate fibrous continuity between the mitral valve and the posterior arterial valve (Fig. 71–6). Following the course of this great artery by gentle clockwise rotation and superior angulation of the transducer allows differentiation between an aorta and a pulmonary artery. An aorta will continue in a cephalad course before it turns posteriorly to become the aortic arch and give off the brachiocephalic branches, whereas a pulmonary artery will dip posteriorly shortly after its origin (Fig. 71–6). A usual, but not consistent, finding is the visualization of both great arteries in a parallel alignment. This is not pathognomonic of transposition of the great arteries since it is often seen in different varieties of double outlet right ventricle. In contrast, in the normal heart with concordant ventriculoarterial connections, the great arteries cross over each other as a result of their spiral relationship.

Defects in the interventricular septum, particularly when there is malalignment of the outlet portion, can also be identified from the parasternal long axis view (Fig. 71–7A). Posterior deviation

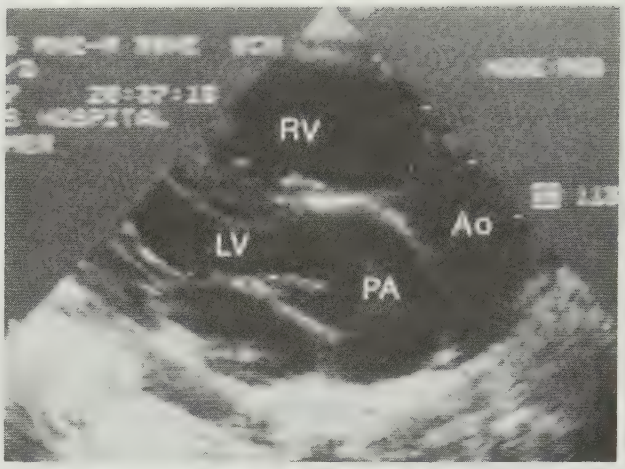

Fig. 71–6. Echocardiography—parasternal long axis view showing the pulmonary artery arising from the left ventricle and the aorta arising from the right ventricle. See Fig. 71–3 for legend to abbreviations.

of the outlet septum in transposition may produce significant left ventricular outflow obstruction (Fig. 71–7B).[62] In the absence of pulmonary hypertension and left ventricular outflow tract obstruction, the left ventricular pressure drops below systemic level beyond the neonatal period. As a consequence, the interventricular septum is usually seen to bulge posteriorly into the left ventricular outflow tract (Fig. 71–8). This is considered to be a result of the reversal of the normal pressure relationship between the right and left ventricles. Systolic anterior motion of the mitral valve may also be seen especially following an atrial baffle operation.

Clockwise rotation of the transducer will lead from a parasternal long-axis to a short-axis view. Cross-sectional imaging of both great arteries in short axis may reveal their abnormal relationship. Normally the pulmonary artery is anterior and to the left of the aorta. In transposition the aorta is generally anterior and to the right of the pulmonary artery (Fig. 71–9). However, it can be found directly in front, anterior, and to the left, or in the side-by-side relationship with the pulmonary artery. By gentle rotation and angulation of the transducer, the course of each great artery can be followed and their bifurcation patterns can be identified.[63] The aorta can be traced from the right ventricle and out of the cross-sectional field. It follows a long course before giving its first branch. The pulmonary artery typically bifurcates before the aorta and its origin from the left ventricle can be traced. This demonstration of ventriculoarterial discordance is essential for the echocardiographic diagnosis of transposition of the great arteries. Defects in the membranous portion of the interventricular septum, as well as patency of the ductus arteriosus, can also be demonstrated in this view. Caudal angulation will produce a short-axis view of both ventricles. Before surgical correction as well as after atrial baffle repair, the right ventricle appears dilated and hypertrophied. The interventricular septum is seen bulging posteriorly. The site of arterial anastomosis after the arterial switch operation is usually seen from the short-axis position.

An apical four-chamber view is obtained by placing the transducer at the apex and aiming medially. Analysis of the crux of the heart will show the normal "offset" between the atrioventricular valves. The tricuspid valve is more apically displaced than the mitral valve. This, together with visualization of dense apical

trabeculations, allows the echocardiographic identification of the morphologic right ventricle. Defects in the inlet, trabecular and membranous portions of the interventricular septum can be profiled from this view (Fig. 71–10), as well as tricuspid valve and mitral valve abnormalities.[64] Cranial angulation of the transducer often shows the bifurcating pulmonary artery connecting to the left ventricle (Fig. 71–11). The interatrial septum is also seen but it is better visualized from the subcostal position. Pulmonary venous connections to the left atrium can be demonstrated. After the Mustard and the Senning operations, the anatomy of the interatrial baffle can be studied and obstruction to pulmonary and systemic venous drainage can be diagnosed (Figs. 71–12 and 71–13).[65,66]

The subcostal view is very helpful for demonstrating atrial structures and the pulmonary and systemic venous connections. Measurements of the interatrial communication before and after balloon or blade atrial septostomy can be performed serially from this angle (Fig. 71–14). A subcostal four-chamber view will provide additional information on the anatomy of the atrioventricular valves and the interventricular septum. From this four-chamber position, anterior angulation together with clockwise rotation of the transducer will profile the left ventricular outflow tract. The connection between the left ventricle and the pulmonary artery can be clearly demonstrated. Counterclockwise rotation from the above position will show the aorta arising from the right ventricle. Obstruction to the right ventricular outflow tract, right ventricular hypertrophy, and dilation are best assessed from this position.[67]

Stenosis of the arterial anastomosis after arterial switch repair can also be visualized from the subcostal window.

The anatomy of the aortic arch is best demonstrated from the suprasternal notch. Though uncommon, an associated coarctation of the aorta must be excluded. The ductus arteriosus is well seen using suprasternal views. Further information on the right and left pulmonary artery branches and the pulmonary venous connections can also be obtained.

It is possible to estimate systemic ventricular function in children with transposition of the great arteries using echocardiographic techniques. Serial assessment of right ventricular performance, especially after the Mustard or Senning operation is particularly useful in the longterm management of these patients. After the arterial switch operation, the left ventricle supports the systemic circulation. Good left ventricular function is important in this group and therefore echocardiographic measurements of left ventricular performance should be routinely obtained.

Pulse wave, continuous wave, and color Doppler echocardiography have added a new dimension to the noninvasive assessment of the patient with transposition of the great arteries. Function of the atrioventricular valves is best evaluated from the apical four-chamber position. These valves are usually normal in transposition. However, tricuspid regurgitation, particularly after atrial baffle repair, is common in the longterm. Doppler evaluation allows serial assessment of tricuspid regurgitation by "mapping" of the retrograde flow within the systemic venous atrium together with the duration and intensity of the regurgitant jet. Careful Doppler interrogation permits differentiation between tricuspid regurgitation and a small ventricular septal defect. The presence of small, multiple, or residual ventricular septal defects can also be evaluated by Doppler techniques (Fig. 71–15).

The right and left ventricular outflow tracts can also be studied with Doppler echocardiography. These areas need to be evaluated from the parasternal position, the suprasternal notch and the subcostal position. Left ventricular outflow tract obstruction is present in children with complex transposition but can also occur in patients with simple transposition both before and after atrial baffle repair (Fig. 71–16). In many cases, this is mild and due to dynamic bulging of the interventricular septum into the left ventricular outflow tract (see Fig. 71–8). In some cases, however, this may be progressive and additional hemodynamic changes may occur on the left ventricular surface of this septal bulge.[68] Doppler echocardiographic determination of the maximum flow velocity in the pulmonary artery provides an easy noninvasive method of assessing the degree of left ventricular outflow obstruction. After arterial switch repair of transposition of the great arteries, stenosis at the site of the arterial anastomosis can occur. The degree of obstruction can be easily quantitated using Doppler echocardiography (Fig. 71–17). Similarly, incompetence of the arterial valves can also be determined.

Flow across the interatrial septum and adequacy of balloon atrial septostomy can also be determined using Doppler echocardiography. Doppler techniques also contribute to the assessment of obstruction within the pulmonary and systemic venous atria after the Mustard and Senning operations. High velocity flows obtained by placing the pulse wave Doppler sample volume at the site of suspected obstruction confirms the diagnosis (see Fig. 71–13).

Apart from providing accurate anatomic and functional information, two-dimensional echocardiography has also altered the management of the newborn with transposition of the great arteries. Some centers will perform balloon atrial septostomy under echocardiographic control in the intensive care unit[69] or may use echocardiographic assistance in the catheterization laboratory, thus minimizing the risk of cardiac catheterization in neonates[70,71] (Fig. 71–18). Arterial switch operations are being performed more frequently in the neonatal period. A thorough echocardiogram may provide the cardiothoracic surgeon with the necessary anatomic information and may obviate the need for cardiac catheterization.

Two-dimensional and Doppler echocardiography represent very powerful tools for the noninvasive assessment of children with transposition of the great arteries. The combination of these techniques significantly reduces the need for cardiac catheterization especially in the newborn as well as in the longterm serial postoperative assessment of children with transposition.

CARDIAC CATHETERIZATION

Preoperative Indications

In the years prior to the 1980s, cardiac catheterization was the only means to make an accurate diagnosis of transposition of the

great arteries. This was often performed as an emergency procedure on an extremely ill hypoxic newborn infant. In many cases only the minimum amount of necessary information was obtained and a balloon septostomy performed. In the 1980s the widespread availability of two-dimensional echocardiography made possible the accurate noninvasive diagnosis of transposition. In addition, the use of prostaglandin E_1 to maintain patency of the ductus arteriosus has provided the physician with the tool to decrease systemic hypoxemia and acidemia and thereby stabilize the sick neonate prior to any procedure. Cardiac catheterization can thus be performed much more safely. The patient is in much better condition and the major diagnosis has been established prior to the onset of the procedure. Thus, although the catheterization will confirm the diagnosis and evaluate for the presence and significance of associated anomalies, the major indication is to perform balloon atrial septostomy. Some centers have demonstrated that balloon atrial septostomy can safely be performed in the intensive care unit solely with echocardiographic guidance.[69,71] This may be valuable in a situation where the cardiac catheterization laboratory is not available and the procedure needs to be performed on an emergency basis. However, most centers still perform balloon atrial septostomy under fluoroscopy in the cardiac catheterization laboratory where all of the tools for diagnosis and management of unexpected emergency situations are readily available. Echocardiographic guidance may be useful, though is not essential in this situation.

Lastly, in considering the indications for cardiac catheterization and balloon artial septostomy in the newborn, one needs to take into account the expected method and timing of surgical therapy. If the patient is clinically stable, has responded to prostaglandin administration, and surgical repair is contemplated within a short period of time, then cardiac catheterization and balloon atrial septostomy are unnecessary. However, if there is concern about possible associated anomalies or if surgical repair is not contemplated for some time, then it is important to perform balloon atrial septostomy to ensure adequate mixing at the atrial level. Once this procedure has been performed it is likely that the patient will then tolerate discontinuing prostaglandin and surgical repair can be performed electively.

In the 1960s and early 1970s a Mustard operation was often performed at 1½ to 2 years of age or even older.[72] In these patients cardiac catheterization was usually repeated between 6 and 9 months of age, or even earlier in the patient with an associated ventricular septal defect. The main indication was concern about the development of pulmonary hypertension or the progressive nature of subpulmonic stenosis. Pulmonary hypertension, though rare in patients with transposition and an intact interventricular septum, was reported in almost every series and there was no way to determine clinically whether or not this problem was present.[73–75] When surgical repair was not performed until after 18 months to 2 years of age, it was not unusual again to perform cardiac catheterization prior to surgery. With the advent of profound hypothermia and circulatory arrest in the early 1970s, most centers began to perform a Mustard or Senning operation at a younger age.[76,77] As the age of operation became earlier in infancy, the concern about pulmonary hypertension diminished and the need for a repeat preoperative cardiac catheterization decreased as well. Currently, repeat cardiac catheterization would only be performed prior to surgical intervention in early infancy if an associated anomaly that would have an influence on the type of operation or its timing needed to be further defined. For example, if a 3 or 4 month old infant with transposition and a ventricular septal defect was being considered for surgical repair and the patient had become more cyanotic, it would be reasonable to be concerned that the patient's ventricular septal defect had become restrictive and that the left ventricular pressure was no longer at systemic level. This would have considerable influence on whether an arterial switch procedure would be performed. In addition, if the ventricular septal defect had become significantly restrictive and the patient no longer had elevation of pulmonary artery pressure, it might be worthwhile to delay surgery and perform an atrial baffle repair possibly without having to close the ventricular septal defect at all.

Postoperative Indications

In many centers, it has been the policy that patients who undergo surgical repair of complex congenital heart disease should have a postoperative cardiac catheterization.[30,78,79] Although two-dimensional and Doppler echocardiography have greatly enhanced the ability for postoperative assessment, in particular with regard to serial evaluations, cardiac catheterization remains the "gold standard" for precise hemodynamic and angiographic evaluation of the postoperative status. In view of the high incidence of electrophysiologic abnormalities, especially in patients who have undergone atrial baffle repair, intracardiac electrocardiographic assessment of sinus and atrioventricular node function has become a part of preoperative and postoperative assessment.[79,80] The postoperative cardiac catheterization in the patient who has had an atrial baffle repair will include specific procedures to evaluate for the presence or absence of pulmonary and/or systemic venous obstruction, as well as for assessment of ventricular function and the adequacy of interatrial or interventricular patches and baffles.[30,78,79] When the patient has undergone an arterial switch operation,[81] the postoperative cardiac catheterization will be used to evaluate stenosis of the anastomotic site of the great arteries, semilunar valve insufficiency, for ventricular function, and for abnormalities of the reimplanted coronary arteries.[82] These postoperative assessments will be described further in this section.

Neonatal Considerations

Cardiac catheterization in the newborn infant requires attention to a number of problems that either are not present or may be less severe outside of the neonatal period.[83] These problems include

1. Severe hypoxemia—careful monitoring of the level of systemic oxygenation is important before, during, and following cardiac catheterization. As a result of the availability prostaglandin E_1, hypoxemia is less of a problem than it has been in the past. As a general rule, a prostaglandin infusion will have been started prior to cardiac catheterization. If not, this drug should be readily available for immediate use during the procedure. An umbilical artery catheter is ideal for monitoring of systemic pressure and blood gases and should be inserted if it is not already in place at the time that the patient arrives in the cardiac catheterization laboratory.
2. Hypothermia—this is a common and potentially lethal problem in critically ill neonates especially when the infant is transported from another outlying hospital. In addition, upon

arrival at the referral center, the infant is usually subjected to multiple examinations, an electrocardiogram, a chest roentgenogram and an echocardiogram, all of which may depress further the patient's body temperature unless adequate precautionary measures are taken. It is thus essential to pay careful attention to the patient's body temperature and use an incubator or other warming device during transport. A radiant heat device should be used to maintain normothermia during examination and while performing procedures prior to cardiac catheterization. In the catheterization laboratory, the infant is placed on a radiolucent heating pad and covered with drapes and towels. Rectal temperature should be monitored continuously during the procedure.

3. Metabolic acidosis—the infant with transposition often has a compensated metabolic acidosis (normal pH with low bicarbonate and low P_{CO_2}). Since the metabolic acidosis may increase during the catheterization, arterial blood should be examined periodically for monitoring of blood gases. Bicarbonate is administered as needed.
4. Congestive heart failure—if present, this should be treated with digoxin and/or diuretics.

Route of Catheter Insertion

In the neonate less than 1 week of age with transposition of the great arteries, it is often possible to insert a soft, flexible, #5 French feeding tube into the umbilical artery. If this is successful, this line can be used to monitor systemic arterial oxygen saturation and pressure during the procedure. In an infant less than 48 to 72 hours of age, the umbilical vein can be used for both the diagnostic catheterization and balloon atrial septostomy.[84–87] Although on occasion we have been able to use the umbilical vein in patients as old as 6 or 7 days, in general the ductus venosus has closed by the third day of life. An advantage of using the umbilical venous route is that it preserves the inguinal region for future catheterizations since ileofemoral venous thrombosis is a common complication following the use of balloon catheters in the inguinal region in the newborn period.[88] A disadvantage of the umbilical approach is that it is sometimes difficult to pass the catheter from the right atrium to the right ventricle, since as the catheter passes through the ductus venosus, it is directed toward the superior portion of the foramen ovale and away from the tricuspid valve orifice.

In using the umbilical venous route, a soft #5 French feeding tube will often easily pass through the ductus venosus and into the right atrium. In contrast, it may be more difficult to pass a woven Dacron catheter or flow-directed balloon catheter through the ductus venosus. To facilitate this catheter movement, the following is recommended: the #5 French feeding tube is first inserted through a #5 or #6 French thin-walled sheath and the sheath is withdrawn back on the feeding tube as far as possible. The feeding tube is inserted into the umbilical vein and passed through the ductus venosus and well into the right atrium. The feeding tube is then held firmly in position and the sheath is advanced over it until the sheath also lies within the right atrium. The sheath is then held in position while the feeding tube is removed and the desired catheter is reinserted through it and passed into the right atrium. If a #5 French woven Dacron catheter is used, a sheath may be left in place or withdrawn onto the shaft of the catheter. If a #6 French sheath is used to enable passage of the larger diameter balloon end of a #5 French flow-directed catheter, then a mismatch will exist between the size of the catheter shaft and the internal lumen of the sheath. In this situation, it is important to withdraw the sheath out of the umbilical vein and back onto the shaft of the catheter. It can then remain in this position until it is again required for catheter exchange. It is often possible to insert a balloon septostomy catheter into the umbilical vein without the assistance of a sheath especially if a Fogarty septostomy catheter (Edwards Laboratories) is being utilized. This type of septostomy catheter has an angled tip that greatly facilitates its making the necessary bend in the ductus venosus. If another septostomy catheter is being used and cannot be passed through the ductus venosus and into the right atrium, it is possible to use the above described technique again with a #7 French sheath if this larger size is required. Another alternative is to use a #7 French sheath at the beginning of the procedure if balloon septostomy is anticipated.

If the umbilical venous route is not utilized, the percutaneous technique is used for catheter insertion into the right femoral vein. The selection of sheath will determine the type of catheter being used and the procedures to be performed. It must be remembered that when a #6 or #7 sized sheath is required for a flow-directed or balloon septostomy catheter, the shaft diameter of this catheter is usually much less than the internal diameter of the sheath required to permit passage of the larger balloon tip. It is therefore mandatory to use a sheath with a backbleed control device such as a Hemaquet (USCI Corporation) to prevent blood loss or accidental aspiration of air and resultant air embolism.

In some cases if the ductus venosus is closed and the percutaneous technique has not been successful, surgical exposure of the femoral vein is required. The site of the skin incision for cardiac catheterization in newborn infants differs from that in older infants and children in whom the saphenous bulb lies 0.5 to 1 cm caudal to the inguinal crease.[83] In newborn infants, the saphenous bulb and saphenofemoral junction lie at about the level of the inguinal crease. Although in the early years of balloon septostomy, Rashkind recommended that the incision be made 1 cm cephalad to the inguinal crease to facilitate insertion of large balloon catheters, it has generally been found that this can be accomplished using the saphenous bulb and saphenofemoral junction. Thus, the skin incision for cardiac catheterization in the newborn infant with transposition is made parallel to and at the level of the inguinal crease. The catheter is usually inserted into the saphenous bulb close to the saphenofemoral junction. The vein at this level is usually large enough to accommodate the 6.5 French tip of the balloon catheter. However, if it is found that the saphenous bulb is too small to admit the desired balloon catheter, it can be inserted into the femoral vein just caudal to the saphenofemoral junction. The saphenous bulb and its tributaries would then be left undisturbed. The femoral vein at this point is large enough and, even though it may have to be ligated after the procedure, collateral channels by way of the long saphenous vein and its branches will allow blood flow to bypass this obstruction and to enter the femoral vein downstream of it. Regardless of whether catheter insertion is near the saphenofemoral junction or in the femoral vein, careful dissection and adequate exposure of the femoral triangle, including the saphenous bulb, all its tributaries, and both proximal and distal femoral vein, are mandatory. Although this will prolong the pro-

cedure, it is time well spent since it is important to be able to control bleeding and identify the proximal and distal ends of an accidentally severed vessel. It will be easier to identify and control the end of the vessel in a well-dissected field than to start the dissection in the midst of massive bleeding from a vessel that is accidentally severed during attempts at insertion of the large end of the balloon catheter. To accomplish this, control ties are usually placed on the saphenous vein just cephalad to the entrance of the last tributaries, and on the femoral vein just proximal and distal to the site of catheter entry.[83] Care is also taken to determine if a deep perforating vessel is present in the region to be used although the site of the vessel is variable. If it is present, it must be controlled, or the femoral blood flow channeled into this vessel will cause considerable bleeding into the operative field.

Diagnostic Cardiac Catheterization

In the years prior to the availability of two-dimensional echocardiography and prostaglandin, cardiac catheterization and balloon septostomy were often performed in a critically ill and hypoxic infant. Today, the diagnosis of transposition of the great arteries is usually established by echocardiography. The infant's condition is stabilized by the administration of prostaglandin to improve systemic oxygenation and the administration of bicarbonate to reverse metabolic acidosis. Thus, baseline hemodynamic data often can be obtained prior to septostomy. If the infant's condition is stable, there is an advantage to obtaining these hemodynamic and angiographic data prior to balloon septostomy in case a problem occurs as a result of this procedure and it is not possible to obtain these data afterwards. Also if the catheterization is being performed by the cutdown technique, there is always the possibility of accidental tearing of the vessel during balloon insertion, which will then prevent reintroduction of another catheter once the balloon catheter has been removed. On the other hand, in the case of a critically ill infant, balloon septostomy should be performed as soon as possible.

Catheter Manipulation

The diagnosis of transposition of the great arteries would be suggested, but is by no means assured, as a result of passage of the catheter from the right ventricle into the aorta. This catheter pass is not diagnostic of a discordant ventriculoarterial connection since it also may be accomplished in patients with truncus arteriosus, tetralogy of Fallot, tetralogy of Fallot with pulmonary atresia, and even in a ventricular septal defect. In patients with transposition and a ventricular septal defect it is often possible to pass the catheter from the right ventricle across the ventricular septal defect and into the pulmonary artery. If the diagnosis of transposition had not been expected, as often occurred in the years before echocardiographic diagnosis of this lesion, this catheter pass might have suggested the presence of a normal ventriculoarterial connection.

The catheter is passed easily from the right atrium to the left atrium across the foramen ovale in the neonate and young infant with transposition and, of course, in those patients who have undergone balloon atrial septostomy. The foramen ovale is usually patent in the newborn with transposition and a ventricular septal defect but will usually spontaneously close during infancy unless a balloon atrial septostomy is performed. In the postoperative patient who has had an atrial baffle repair, the catheter passes easily from the inferior vena cava across the region of the baffle and into the portion of the systemic venous atrium that lies just above the mitral valve. Entry into the superior vena cava is a bit more difficult and requires that the catheter be passed along the convex lateral surface of the baffle before it enters the superior vena cava. In these postoperative patients, it is also possible to enter the pulmonary venous atrium and directly measure the pressure in the pulmonary veins. This is accomplished by passing a loop of a retrograde arterial catheter across the aortic valve into the right ventricle and then manipulating this loop in retrograde fashion across the tricuspid valve and into the pulmonary venous atrium.

In the patient with transposition, both preoperatively and following atrial baffle repair, the catheter pass from left ventricle into the pulmonary artery is difficult and requires the use of a flow-directed balloon catheter. In the past, it was possible to enter the pulmonary artery using flow-directed polyethylene tubing or following intense manipulation of a woven Dacron catheter. For the latter technique the catheter tip was positioned in the right upper pulmonary vein and the catheter advanced until a loop had formed. This loop was then backed across the mitral valve and after considerable manipulation it was often possible to pass the tip of this catheter into the pulmonary artery. These techniques are mentioned for historical interest only since the flow-directed balloon catheter is now the preferred method.

Unfortunately, in some cases, the standard flow-directed balloon catheter as it comes from the factory is too straight to pass easily across the atrial septum. Also, in the small infant, the very straight catheter often wedges in the apex of the left ventricle rather than making the necessary bend required to pass out into the pulmonary artery. We have found it extremely helpful to prepare all of our flow-directed balloon catheters, both the end-hole type and the angiographic closed end type, with a preformed curve at the tip. This is accomplished with balloon catheters in the same manner as with woven Dacron catheters. A thin curved wire is inserted into the lumen of the end-hole type catheter while a piece of small plastic tubing is passed over the angiographic balloon catheter and an appropriate curve formed with a piece of tape. These catheters are then re-sterilized and the resulting preformed curves greatly facilitate their manipulation across the atrial septum, through the left ventricle, and out into the pulmonary artery.

Oximetry

Oxygen saturation is measured in the superior vena cava, aorta, pulmonary artery, and pulmonary veins. If oxygen consumption is also measured then pulmonary and systemic blood flow as well as effective pulmonary blood flow can also be determined. The method for doing these calculations is described in the chapter on hemodynamic measurements during cardiac catheterization. A characteristic finding in the patient with transposition of the great arteries, and not usually found in patients with other abnormalities, is the presence of an oxygen saturation in the pulmonary artery that is much higher than that in the aorta. In addition, the extremely high pulmonary artery saturation found in patients with an intact interventricular septum results in a small pulmonary arteriovenous oxygen saturation difference. Thus, it must be remembered that small errors in measurement result in a large difference in the calculated pulmonary blood flow. It is also worth noting that the effective pulmonary blood flow is usually less than 20% of the

total pulmonary flow thus indicating that a relatively small percentage of the total pulmonary flow is actually participating in systemic oxygenation.[89]

Hemodynamics

In the neonate with transposition, the pressures in the ventricles and great arteries are generally equal in the first few days of life. After about 48 to 72 hours the pulmonary artery pressure begins to fall and is generally at about two-thirds of systemic level by 4 to 5 days of age and continues to fall progressively during the first month of life. This change, which parallels the decrease in pulmonary vascular resistance found in the normal newborn, occurs in the patient with transposition and an intact interventricular septum.[54] In contrast, in the patient with an associated unrestrictive ventricular septal defect, the pulmonary artery pressure remains at systemic level. This is also true when a substantial ductus arteriosus remains patent after the first few days of life. Pulmonary hypertension is of serious concern in the patient with transposition and even may be found in the patient with an intact interventricular septum.[73] If an operative repair is not performed in the early months of life, it is recommended that cardiac catheterization be performed prior to 6 months of age to measure pulmonary artery pressure. If elevated, this would be a strong indication for the patient to undergo repair, or in the presence of an associated complex ventricular septal defect, to undergo pulmonary artery banding.

An interatrial gradient is usually found prior to balloon septostomy and may be only a few mm Hg or more than 10 mm Hg. A successful balloon atrial septostomy will abolish the interatrial gradient or at most leave a residual gradient of only a few mm Hg.[90]

Subpulmonic stenosis is often found in the patient with transposition of the great arteries. When combined with an associated ventricular septal defect the subpulmonic stenosis is often severe and the patient would be classified in the complex transposition category. In the patient with an intact interventricular septum, there is usually no left ventricular outflow tract gradient in the newborn period.[30,54] However, as the left ventricular pressure falls during the first month of life, the difference between the right and left ventricular pressure results in a bowing of the interventricular septum toward the left ventricle, which produces a dynamic form of left ventricular outflow tract obstruction. It is common to find a 20 to 30 mm Hg left ventricular outflow gradient in these patients without the presence of any fixed valvar or subvalvar pulmonary stenosis.[30] If the left ventricular pressure is elevated above 40 mm Hg beyond the newborn period, it is mandatory to measure the pressure in the pulmonary artery to be certain that this elevation is the result of left ventricular outflow obstruction rather than pulmonary hypertension. If the left ventricular pressure is elevated to greater than two-thirds of the systemic level, it is important to document the cause of obstruction angiographically. Although we have seen patients with a dynamic form of outflow tract obstruction with left ventricular pressure at systemic level and little or no heart murmur, it is more common to find some form of fixed obstruction in the presence of high left ventricular outflow tract gradients.

Angiocardiography

The left ventricular angiocardiogram is diagnostic for transposition of the great arteries, in particular, when there is an intact interventricular septum (Fig. 71–19). This injection will demonstrate the discordant ventriculoarterial connection and there is no other anatomic abnormality where the pulmonary artery would be the only great vessel filled following a left ventricular injection. In contrast, although the aorta will fill from the right ventricular injection in the patient with transposition, this also occurs in patients with tetralogy of Fallot and pulmonary atresia or in truncus arteriosus. The morphologic characteristics of the ventricles are normal in the patient with transposition. Thus, the right ventricle is triangular in shape and heavily trabeculated with a vertically oriented atrioventricular valve, while the left ventricle is oval in shape with a smooth surface and an atrioventricular valve that is obliquely oriented across the outflow tract.

The origin of the left pulmonary artery from the main pulmonary artery may be at a very acute angle in the patient with transposition. The left ventricular outflow is thus preferentially directed toward the right pulmonary artery.[55] This often results in as much as two-thirds of the pulmonary artery flow going to the right and only one-third going to the left. This may be apparent either by the difference in size between the two pulmonary artery branches or by the increased opacification of the pulmonary arteries in the right lung as compared to the left.

A number of abnormalities found in association with transposition of the great arteries can be defined angiographically. A patent ductus arteriosus is commonly present in the newborn period but if it persists and is large, it may result in pulmonary hypertension and/or congestive heart failure. In addition, even a relatively small patent ductus arteriosus may mask the clinical findings of an accompanying coarctation of the aorta. A right ventricular angiocardiogram may adequately demonstrate the aorta when the interventricular septum is intact. On the other hand, in the presence of a ventricular septal defect, the left side of the heart and pulmonary artery will fill almost simultaneously and thus a selective injection in the aorta is essential. An injection in the ascending aorta with the catheter just above the aortic valve will generally not only be adequate to demonstrate the anatomy of the aortic arch, its branches, and the thoracic aorta, but will also demonstrate coronary artery anatomy in the patient being considered for an arterial switch operation. Ideally, if the total volume of contrast being used was not a concern, a selective injection in the frst portion of the descending thoracic aorta, at the site of origin of the ductus arteriosus, is best for visualization of that region.

A selective right ventricular angiocardiogram is usually performed to visualize an accompanying ventricular septal defect. In the heart with normally connected great arteries, a ventricular septal defect is best visualized in the four-chamber view (left anterior oblique with cranio-caudal angulation), or in the long axial (tilted left anterior oblique) view. Although the interventricular septum is oriented more toward the lateral plane in transposition, the ventricular septal defect will still adequately be visualized in the four-chamber view. However, on occasion it may be necessary to use more than the standard 60° of left anterior oblique. When there is pulmonary stenosis accompanying a ventricular septal defect, especially if the degree of obstruction is moderately severe and there is little or not shunt from right ventricle to left ventricle, it may be necessary to perform a selective left ventricular injection in order to visualize better the ventricular septal defect. In these cases as well the four-chamber view often is best to visualize the defect.

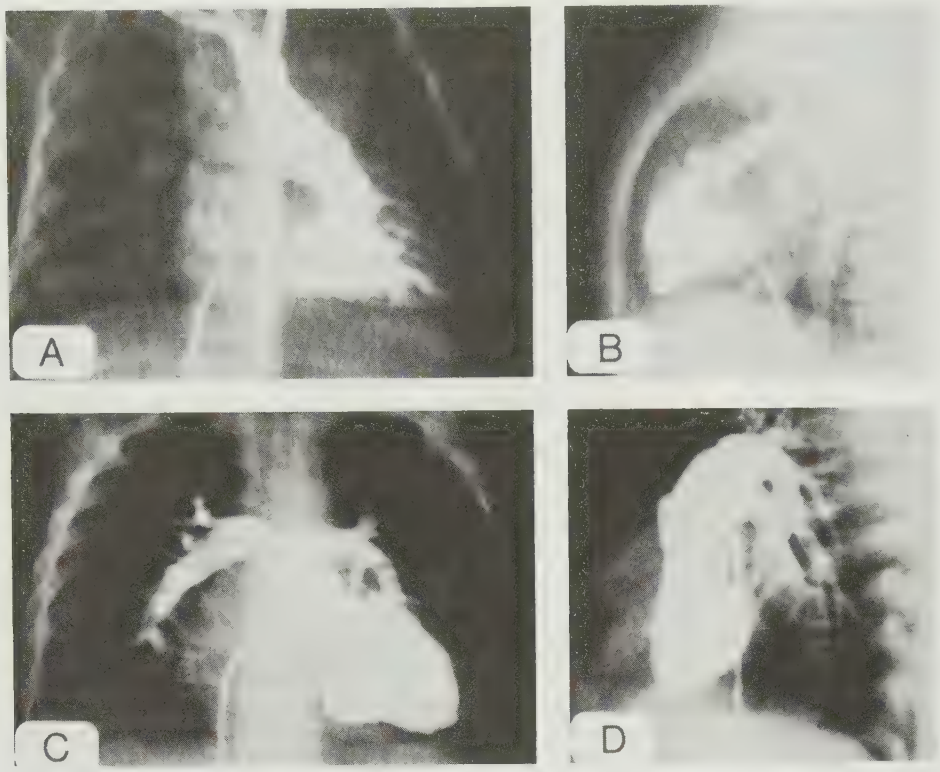

Fig. 71–19. Angiography in transposition of the great arteries. Top: right ventricular angiocardiogram in posteroanterior (A) and lateral (B) views. Bottom: Left ventricular angiocardiogram in posteroanterior (C) and lateral (D) views.

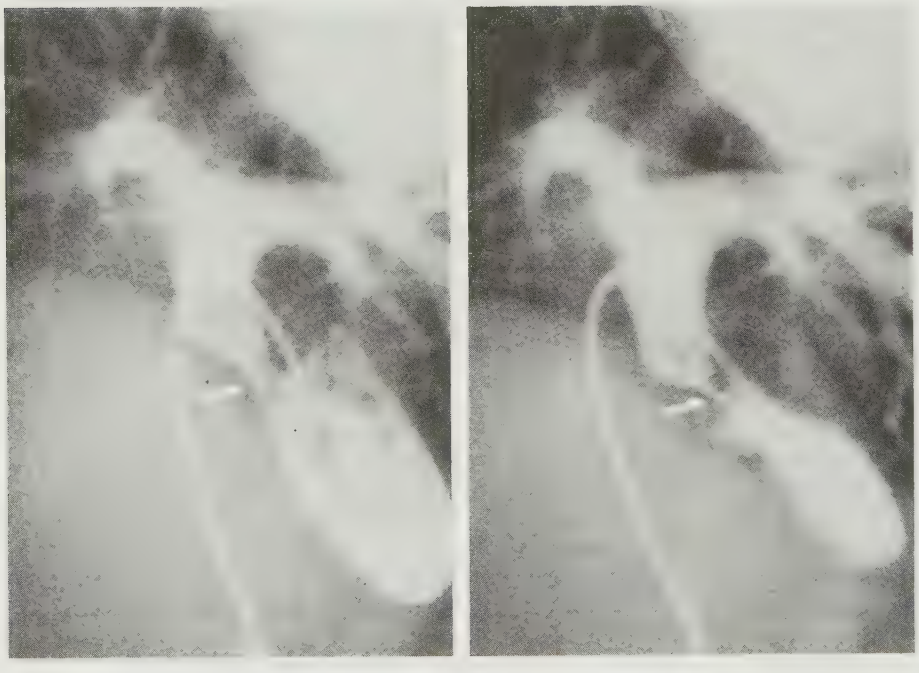

Fig. 71–20. Left ventricular outflow obstruction in transposition of the great arteries (arrows). Left: diastole, right: systole.

The anatomic cause of left ventricular outflow tract obstruction can be demonstrated by a selective left ventricular injection (Fig. 71–20). This can be accomplished with either a four-chamber or long-axial view,[36] although we generally prefer to use the four-chamber view. While mild to moderate gradients are generally produced by the dynamic form of left ventricular outflow tract obstruction, more severe obstruction with left ventricular pressure greater than two-thirds of systemic level is more often caused by a fixed obstruction. These include a discrete fibromuscular subpulmonic shelf, valvar pulmonic stenosis, pulmonary artery stenosis, and on occasion pieces of atrioventricular valve tissue. This latter form may be due to a so called "aneurysm of the ventricular septum" which is formed from pieces of redundant tricuspid valve tissue that prolapse through the ventricular septal defect into the left ventricular outflow tract (Fig. 71–21). It is also possible to have redundant portions of mitral valve tissue that behave in a similar fashion. In both cases, in particular, when this structure is related to the mitral valve, it is important to document its origin as best as possible prior to operation. Wide surgical excision of obstructing atrioventricular valve tissue may relieve the subpulmonic obstruction but may also result in significant atrioventricular valve regurgitation postoperatively.

Electrophysiologic Studies

In the majority of patients with transposition of the great arteries with intact interventricular septum, ventricular septal defect, or in complex situations, the electrical system of the heart appears to be intact prior to operation. Atrial and ventricular arrhythmias are uncommon as are disorders of atrioventricular conduction. First degree AV block is unusual while second and third degree AV block are rare preoperatively. We have performed some simple intracardiac electrophysiologic studies in preoperative patients with transposition over the last decade.[80] AH and HV intervals are usually normal as is sinus node recovery time. Stress of the AV conduction system by rapid atrial pacing has demonstrated normal function with almost all patients conducting normally at atrial pacing rates over 180 to 200 beats per minute. Similarly, other reports have described normal atrial, AV nodal, and ventricular refractory periods in preoperative patients.

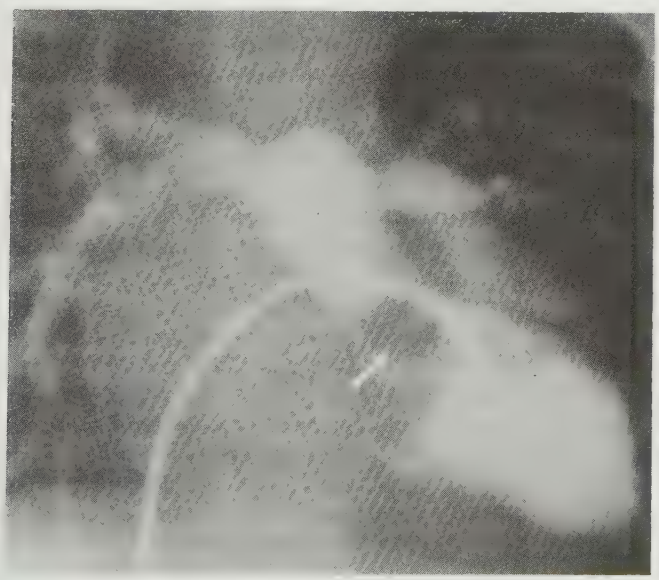

Fig. 71–21. Left ventricular angiocardiogram demonstrating an "aneurysm of the ventricular septum" (arrow) causing subpulmonic obstruction.

Although many centers began to perform the Mustard operation in the mid 1960s, it was not until the early 1970s, some 6 to 7 years later, that reports began to appear of atrial arrhythmias in longterm survivors.[78,91] It was common to see junctional rhythm with AV dissociation or junctional tachycardia in the early postoperative period. However, in most cases these abnormalities resolved and patients were thought to be in sinus rhythm. El-Said et al.[91] reported that the P-wave morphology was abnormal in postoperative patients and suggested that these were ectopic atrial foci and that a true sinus mechanism did not exist. Destruction of the sinoatrial node was demonstrated in post mortem specimens of postoperative patients and it was suggested that this, in combination with destruction of interatrial bypass pathways, was responsible for the disorders seen postoperatively.[18,91] Since that time many reports have demonstrated abnormalities on intracardiac electrophysiologic studies in patients who have had interatrial baffle repair, particularly the Mustard operation.[80,92–96] Sinus node recovery time is often abnormal and interatrial conduction may be impaired. Even patients who have an apparently normal electrocardiogram and normal 24 hour ambulatory monitoring may show abnormal sinus node function or have prolonged atrial refractory periods. Abnormal atrioventricular node function is much less common but a small percentage of patients have prolonged HV intervals, or abnormal AV node refractoriness, or in some cases third degree atrioventricular block. In general, it is more common to find these abnormalities of atrioventricular node function in patients with more complex forms of transposition who have required ventricular septal defect repair or a Rastelli operation. In contrast, atrial arrhythmias are usually found in patients who have had an atrial baffle type of repair.

CATHETER SEPTOSTOMY—TECHNICAL ASPECTS

The development of balloon atrial septostomy, by Rashkind and Miller in 1966,[10] was an important historical milestone since this was the first therapeutic interventional procedure performed in the cardiac catheterization laboratory. In the years since its introduction, balloon atrial septostomy has been successfully used worldwide and is considered to be the procedure of choice for creation of an interatrial communication in all newborn infants with transposition of the great arteries.[90,97–99] However, beyond the newborn period, it is usually difficult to create an adequate interatrial communication largely related to a thickened interatrial septum that cannot successfully be torn by a balloon. Blade atrial septostomy was developed by Park in 1975[100] to overcome the limitations of using the balloon catheter alone to try to create an interatrial communication outside the newborn period. It is now possible by using these procedures alone, or in combination, to create an interatrial communication without thoracotomy in patients at any age and even when the atrial septum is initially intact.[101–103]

Balloon Atrial Septostomy

Types of Balloon Septostomy Catheters

Early Rashkind balloon septostomy catheters were available as

either a single lumen catheter with a balloon at the tip or as a double lumen catheter with the distal end-hole connected to one lumen and a slightly more proximal side-hole connected to the balloon. These catheters had a bulky, irregular balloon section that often made it difficult to introduce the catheter into the femoral vein. The balloons did not inflate in a symmetrical, round fashion and were often "sausage shaped" and eccentrically positioned to one side of the catheter. It was not unusual to have a balloon rupture and, on at least one occasion in our series, the proximal balloon tie slipped distal to the side hole making it impossible to deflate the balloon. Over the years, the construction and quality of balloon catheters has improved considerably. The current Rashkind septostomy catheter (USCI) has a recessed balloon and can be passed through a #6 French percutaneous sheath (Fig. 71–22). The balloon has the capacity of 2 mL and its maximum inflated diameter is 12 mm. The Fogarty septostomy catheter (American Edwards Laboratory) has a 1.8 mL capacity, a slightly larger maximum inflated diameter than the Rashkind catheter, but the tip is approximately 6.5 French and therefore this catheter must be inserted through a #7 French sheath (Fig. 71–22). The Fogarty septostomy catheter is manufactured with the balloon section at approximately a 45° angle to the shaft of the catheter. Within the balloon segment the catheter tip is connected to the shaft by a coil spring device. This unique construction provides considerable flexibility of the catheter tip and makes it easy for fluid to pass in and out of the balloon. This angled, flexible catheter tip greatly facilitates passage of the catheter across the atrial septum and also makes it much easier to manipulate this catheter through the ductus venosus as compared to the straight and more rigid Rashkind type catheter. These advantages of the Fogarty catheter outweigh its disadvantages of requiring a larger size sheath or the increased difficulty of inserting it directly into a small size femoral vein. Thus, while both catheters are available in our laboratory, the Fogarty septostomy catheter is preferred whenever its use is possible. A larger balloon septostomy catheter, the Miller catheter (American Edwards Laboratory), is also available. It has a 4 mL capacity and has a maximum inflated diameter of 16 mm. This catheter also requires #7 French sheath and is most useful when a larger interatrial communication is required, such as in a patient beyond the newborn period who is undergoing a balloon atrial septostomy.

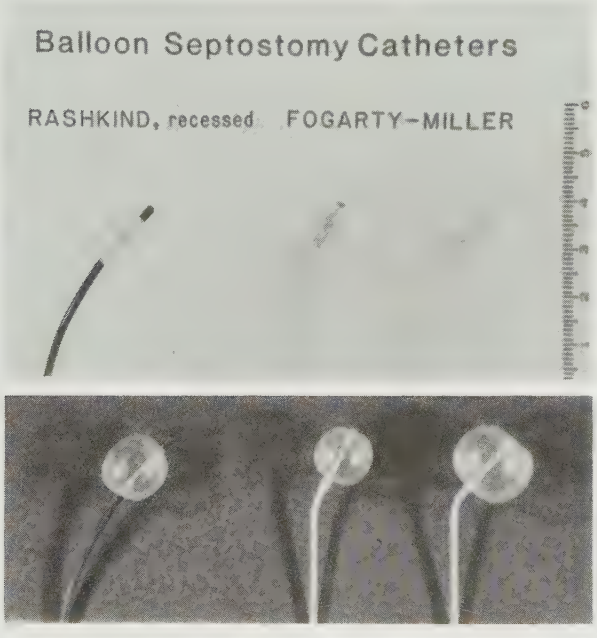

Fig. 71–22. Balloon septostomy catheters illustrating before (top) and after inflation (bottom).

Balloon Septostomy Procedure

Introduction of the balloon septostomy catheter in the inguinal region, either by the percutaneous sheath technique,[99] or if necessary by cutdown,[83] is the conventional approach. Insertion of the catheter into the umbilical vein and its passage through the liver via the ductus venosus is often possible in the infant under 3 or 4 days of age.[84–87] We would recommend an attempt to use the umbilical vein, if it is patent and accessible, in the infant under a week of age, since on occasion the ductus venosus has been found to be patent even on the sixth day of life. Although the umbilical venous route may be demonstrated angiographically to be open, there is a sharp angulation where the umbilical vein joins the ductus venosus and it may be difficult to pass the catheter across this area. However, we have found that it is generally possible to use a Fogarty balloon septostomy catheter via the umbilical venous route when it has also been possible to pass a feeding tube or a woven Dacron catheter through this area. If it is not possible to pass the balloon septostomy catheter, the necessary sized sheath can be introduced using a feeding tube by the technique that has been described above in the section on cardiac catheterization. Despite these difficulties of catheter insertion, the umbilical venous route has been as effective and safe as the femoral venous approach. It must be remembered whenever a sheath is used, regardless of whether through the umbilical vein or the femoral vein, a sheath with a backbleeding control device must be used to prevent excessive blood loss or the possibility of air aspiration into the circulation.

Once the decision has been made to proceed with balloon septostomy, a balloon septostomy catheter is inserted into the venous system, advanced to the right atrium and passed across the foramen ovale into the left atrium. It is important that the operator be certain that the catheter tip is positioned in the left atrium prior to balloon septostomy. What may appear to be a normal right-to-left atrial catheter pass in the anteroposterior view may, in fact, be a pass into the right ventricle, left ventricle, or right atrial appendage, especially when juxtaposition of the atrial appendages is present.[104,105] To avoid the potentially hazardous withdrawal of an inflated balloon from one of these areas, which might result in avulsion of an atrioventricular valve or atrial tear, the position of the catheter tip within the left atrium must be confirmed prior to balloon inflation and the septostomy procedure. This is accomplished by passing the tip of the balloon catheter past the left heart border and into a pulmonary vein. The posterior position of the catheter tip is confirmed fluoroscopically in the lateral view. If the catheter tip has been advanced into the right or left ventricle it will be directed anteriorly rather than posteriorly on the lateral view. In addition, premature ventricular contractions may be stimulated if the catheter is tapped against the heart wall. A catheter positioned in the right atrial appendage or left atrial appendage will bounce vigorously while a catheter tip appropriately posi-

tioned in the pulmonary vein will hardly move at all. Thus, a catheter tip that is beyond the left heart border and showing very little vertical movement in the anteroposterior view, which is also positioned posteriorly in the lateral view, is properly positioned in a pulmonary vein. The catheter is then withdrawn until it is inside the left heart border with the tip positioned between the left heart border and the vertebral column. The balloon is then slowly inflated while this maneuver is being monitored fluoroscopically. If the balloon is difficult to inflate or is inflating in an elongated rather than a round fashion, this may indicate that it is positioned in the pulmonary vein. If this occurs the balloon must be deflated, the catheter withdrawn slightly, and then inflation again attempted. Careful attention must be paid to this maneuver since full inflation of the ballon in a pulmonary vein or the left atrial appendage may result in inadvertent rupture of these structures.

It is also possible to use two-dimensional echocardiography to determine that the catheter is appropriately positioned within the left atrium. Some centers have recommended echocardiography as the sole imaging method for balloon atrial septostomy in the newborn nursery or intensive care unit, while others have suggested combined echocardiographic and fluoroscopic guidance in the cardiac catheterization laboratory.[69–71] Although each of these methods has its advantages and disadvantages, it is still generally preferred to perform balloon atrial septostomy in the cardiac catheterization laboratory. Regardless of which imaging technique is utilized, the operator must pay careful attention to details such as the position of the catheter tip within the left atrium and initial slow inflation of the balloon to avoid injury.

As the balloon is inflated under direct vision, either by fluoroscopy or echocardiography, the catheter is slightly withdrawn to ensure that the balloon is being inflated within the left atrium. The balloon should be inflated to the maximum desired diameter for the initial withdrawal. In the newborn, the appropriate balloon diameter is approximately the same size as the side-to-side width of the patient's vertebral column. This is generally achieved by using the recommended maximum inflation volume. For example, with a #5 French Fogarty septostomy catheter, an inflation volume of 1.8 mL results in a balloon diameter of about 15 mm. In smaller neonates, including premature infants, the desired inflation diameter of the balloon occurs with less volume. It has been suggested by some investigators that an initial septostomy be performed with a less-than-maximum balloon diameter, with the balloon progressively inflated for successive withdrawals. This technique runs the risk of simply stretching the interatrial communication, rather than tearing of the valve flap of the foramen ovale, which is the desired result. It is therefore recommended that the maximum desired balloon inflation diameter be used for the initial, as well as successive, withdrawals.

As the balloon is inflated within the left atrium, it is generally withdrawn against the atrial septum until the appropriate diameter has been achieved. The catheter is then withdrawn from the left atrium to the right atrium with a rapid, short, jerking motion. This maneuver will tear the valve of the foramen ovale and it is again important to stress that this tear should occur on the first withdrawal (Fig. 71–23). A few additional withdrawals are often performed and may slightly extend the tear that was started with the first pullback.

The early results of balloon atrial septostomy are assessed on the basis of changes demonstrated in the catheterization laboratory, echocardiography and, of course, clinical improvement. It is common to find a pressure gradient between the left and right atrium before balloon septostomy and this gradient should be abolished or minimized by the procedure (Fig. 71–24). A satisfactory balloon septostomy should result also in either a rise in systemic atrial oxygen saturation of 10%, or an arterial oxygen saturation of greater than 60%.[97,98] Improvement in systemic arterial oxygen saturation is most pronounced in the patient with transposition and an intact interventricular septum. In the presence of a ventricular septal defect, the systemic arterial oxygen saturation may be high before septostomy and thus it is possible that little or no change may occur following the procedure. Although an oxygen saturation of 60% of greater is a criterion for an adequate balloon septostomy result, a saturation below this level may be found in patients with adequate palliation who do not require additional surgical intervention.[106] Echocardiography is extremely valuable to assess the result of balloon atrial septostomy. The atrial septum is easily visualized from the subcostal approach and an adequate balloon septostomy should result in an atrial septal communication that measures at least 8 mm in diameter echocardiographically (see Fig. 71–14).

There is a small group of patients who do not show clinical improvement despite having had an apparently successful balloon septostomy as evidenced by a reduction or elimination of the interatrial gradient and echocardiographic demonstration of an adequate atrial septal opening. Some of these patients will improve in the 48 to 72 hours following septostomy. The remaining small number of patients have some deficiency in atrial mixing that is not readily explained but is thought to be due to preferential flow of the pulmonary venous return toward the mitral valve. In some cases this may be improved by volume expansion and continued prostaglandin administration. Those patients with continued poor atrial mixing despite these measures may not be improved further even by blade septostomy or by Blalock-Hanlon atrial septectomy. These patients usually required early operation which, in the past, was an atrial baffle procedure.

Blade Atrial Septostomy

Although the initial balloon septostomy may appear to be successful in the vast majority of patients with transposition of the great arteries, the interatrial communication may subsequently be found to be inadequate in up to 20% of cases. Repeat balloon septostomy, or even a primary procedure toward the end of the first month of life, is generally unsuccessful largely due to a thickened interatrial septum which cannot be torn effectively by a balloon catheter.[97,98] Blade atrial septostomy was developed to overcome this limitation of a balloon septostomy. The clinical use of blade septostomy in a limited number of patients was first reported by Park et al. in 1978.[101] An extensive collaborative study among multiple centers was reported in 1982 and established the efficacy and safety of this procedure.[102] Blade atrial septostomy is now widely utilized both in the United States and abroad in the management of patients with transposition as well as a wide variety of other disorders.[103]

Procedure and Technique

The blade septostomy catheter is currently available (Cook, Inc.) in 9.4 mm, 13.4 mm, and 20 mm lengths. The smaller catheter is generally adequate for use in infants while the larger

catheters are used in older patients in whom a larger interatrial communication is required. The blade catheter has a long straight metal component at the tip that is angulated at about 25° to the catheter shaft (Fig. 71–25). Unfortunately, this degree of angulation is still not sufficient to permit easy passage of the catheter tip across the atrial septum into the left atrium in many cases. This is particularly true in the patient with a small left atrium or when there is an unusual location of the interatrial communication. It is thus recommended that a long percutaneous sheath (Mullins transseptal sheath, USCI) be utilized to introduce the catheter tip into the left atrium (Fig. 71–26). Prior to use, the length of the sheath should be compared to that of the balloon and blade catheters to ensure that the working portion of the catheter will protrude beyond the distal end of the sheath. If the sheath is found to be too long, it can be cut back to an appropriate size using a scalpel blade. To permit easy manipulation of the blade catheter within the sheath, a #7 French sheath is recommended for the blade septostomy procedure. This will also eliminate the need to change the sheath if a Fogarty catheter is used for the subsequent balloon septostomy. In performing blade and balloon septostomy, it is preferable to use a sheath with a side port and a backbleeding control device. This will permit intermittent or slow continuous infusion of heparinized flushing solution through the side port of the sheath during the procedure. This infusion, in combination with the backbleed control mechanism, will prevent either the possibility of air aspiration due to air entrapment during catheter exchange, excessive blood loss, or thrombus formation within the sheath.

The sheath is initially introduced into the right atrium using a guidewire and its long dilator (Fig. 71–26:1).[103] The guidewire and dilator are removed and a regular woven Dacron catheter is introduced into the sheath and passed into the left atrium (Fig. 71–26:2). The sheath is then advanced over the catheter into the left atrium and the catheter is withdrawn, thus leaving the tip of the sheath within the left atrium (Fig. 71–26:3). The blade septostomy catheter is then passed through the sheath into the left atrium (Fig. 71–26:4). The sheath is withdrawn while the tip of the blade catheter remains within the left atrium. The blade component is opened and the catheter rotated in a counterclockwise direction so that the blade faces anteriorly in the lateral fluoroscopic view. The catheter is then slowly withdrawn and a gentle but steady force is maintained until a sudden loss of resistance is felt and the catheter passes into the right atrium (Fig. 71–26:5). If the atrial septum is thickened and unusually tough, the blade may reach to the level of the diaphragm before it "pops free." It is important to remember that septostomy with a blade catheter is performed using a slow, steady withdrawal as compared to the rapid, sudden jerking motion of balloon atrial septostomy. Blade septostomy is safely performed as long as resistance is met in the usual mid-portion of the atrium and there is no loss of resistance or sudden change of angulation during slow catheter withdrawal. Several passes of the blade catheter across the atrial septum should be performed with a slightly different angulation each time to ensure an adequate tear. After this has been accomplished, the blade catheter is withdrawn and a balloon septostomy catheter is then introduced into the left atrium (Fig. 71–26:7). Balloon septostomy is performed in the usual fashion, thus further enlarging the newly created interartial communication (Fig. 71–26:8). It is important to emphasize that, during blade or balloon septostomy, the sheath and the septostomy catheter must be pulled together in unison so that the distal tip of the long sheath is not damaged during the septostomy procedure.

Malfunction of the blade septostomy catheter has occurred occasionally. This has usually been because of difficulty in retracting the blade component back within the catheter lumen and is probably related to opening the blade section beyond the recommended maximum angle. To avoid this problem, careful inspection of the blade septostomy catheter and trial attempts at opening the blade and evaluating the maximum angle are essential prior to introduction of the catheter into the patient. Also, intermittent or slow continuous infusion of heparinized fluid through the side port of the blade catheter will prevent clot formation, a problem that might interfere with retraction of the blade component into the catheter lumen.

MANAGEMENT OF THE PATIENT WITH TRANSPOSITION OF THE GREAT ARTERIES

The introduction of balloon atrial septostomy in the mid-1960s was the single most important factor to influence the survival of the infant with transposition of the great arteries. Many other milestones have occurred over the four decades since the first systemic to pulmonary artery anastomoses were developed (Table 71–1). Over the years as these various improvements in management became available, the age at which repair of transposition is performed has become progressively younger. Today, most centers would attempt repair of transposition in the early months of life. This change in management from an invariably fatal congenital malformation for which nothing could be done, to the current era of arterial switch procedures and neonatal repair, is best demonstrated by examining the natural history of patients with this anomaly and how it has been modified by the advances of medical and surgical therapy over the last four decades.

Natural History and its Modification by Therapy

To best assess the effect of medical and surgical management on the natural history of transposition of the great arteries, it is worthwhile to consider the morbidity and mortality of infants in

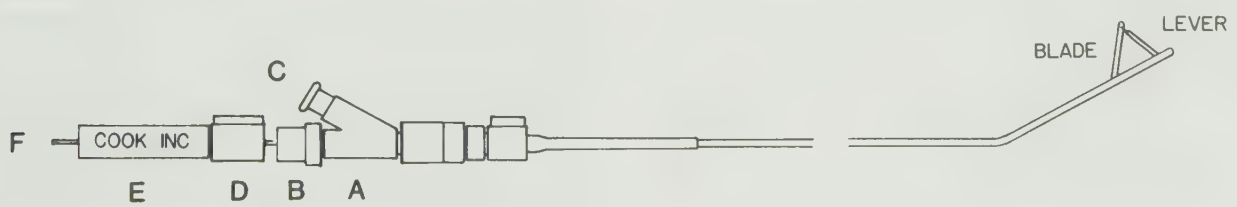

Fig. 71–25. Diagram of a blade septostomy catheter.

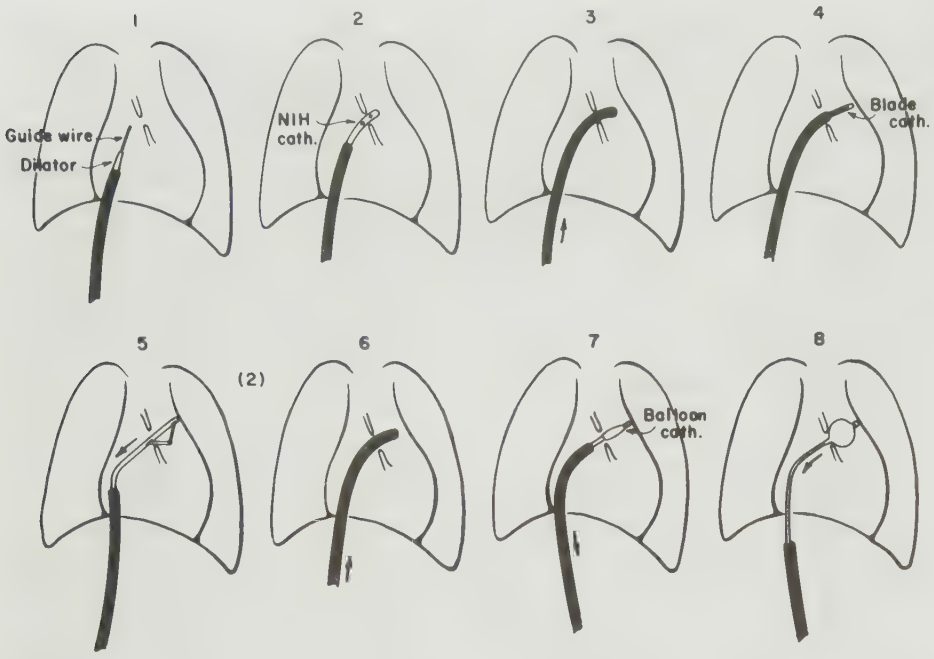

Fig. 71–26. Diagrams illustrating the use of a long sheath for blade and balloon atrial septostomy (see text for description of procedure).

the first year of life. The last four decades span major eras in the management of infants with transposition. The first period, prior to 1950, is an era during which surgical therapy essentially was not available. Although palliative surgical options were first made available in the late 1940s,[107,108] very few centers had surgeons trained in these techniques and thus management was generally nonsurgical, and patients with this diagnosis usually died. In two large series reported by Liebman[3] and by Shaher,[5] about 90% of patients with transposition and intact interventricular septum died in the first year of life. These patients usually succumbed to the effects of hypoxemia and congestive heart failure. Patients with transposition and a ventricular septal defect usually lived somewhat longer since they have less problems with severe hypoxemia. However, mortality was high due to congestive heart failure. A few patients did survive when their pulmonary blood flow became reduced to more tolerable levels by the development of pulmonary vascular obstructive disease. Patients with complex transposition, those with a ventricular septal defect and accompanying pulmonary stenosis, had the best survival since excessive pulmonary blood flow was not a problem, and those with moderate pulmonary stenosis did not require surgery. Patients with severe pulmonary stenosis or pulmonary atresia usually died, but some were salvaged by systemic-to-pulmonary artery anastomoses toward the end of that period.

Table 71–1. Chronology of Management of Transposition of the Great Arteries

Presurgical: Prior to 1950
1945: Blalock-Taussig[107] and Potts[108] anastomoses
Palliative surgical: 1950–1963
1950: Blalock-Hanlon atrial septectomy[7]
1952: Pulmonary artery banding[109]
1956: Baffes procedure[112]
1959: Senning operation[8]
1962: Waterston/Cooley anastomosis[110,111]
Surgical repair: 1964–1973
1964: Mustard operation[9]
1966: Rashkind balloon septostomy[10]
1969: Rastelli operation[113]
1970–1973: Profound hyperthermia[114,115]
Repair during infancy: 1974–1983
1975: Park blade septostomy[100]
1976: Jatene arterial switch operation[81]
1977: Prostaglandin E_1[116,117]
1977: Senning operation (revival)[118]
Current era of management: 1984–Present
Atrial baffle vs. arterial switch

The natural history of transposition of the great arteries was gradually modified during the period from 1950 to 1963. During this pre-repair era, there was a proliferation of cardiac surgical centers. The widespread availability of the Blalock-Hanlon atrial septectomy,[7] pulmonary artery banding,[109] and systemic-to-pulmonary artery anastomoses[107,108,110,111] resulted in a considerable increase in the survival of patients with transposition. The Baffes procedure, described in 1956, consisted of a transfer of the inferior vena cava to the left atrium and the right-sided pulmonary veins to the right atrium.[112] This was attempted by some but was largely unsuccessful. Although Senning's operation had been described in 1959, it also was generally unsuccessful and was thus abandoned.[8] The next era of management from 1964 through 1973, marked the introduction of balloon atrial septostomy,[10] Mustard's operation,[9] and the Rastelli procedure.[113] These procedures dramatically altered the survival and prognosis of patients with transposition, especially those with an intact interventricular septum. This resulted in a much more aggressive approach to the management of the newborn and small infant with this disorder.

In the fourth period, 1974 through 1983, repair of transposition during the first year of life became common through the widespread use of profound hypothermia and circulatory arrest.[114,115] The introduction of prostaglandin E_1 provided a pharmacologic means of improving oxygenation of newborns until palliative or

definitive procedures could be performed.[116,117] The development of blade atrial septostomy[100] and the arterial switch[81] procedures during this period further influenced the already modified natural history of patients with this disorder. In the early 1980s, the previously abandoned Senning operation gained popularity and most centers began to use it in preference to the Mustard operation.[118]

Although the major advances in therapy have been outlined above, it must be remembered that many improvements in other areas had a profound influence on the management, morbidity, and mortality of infants with transposition. For example, in the early 1970s it was recognized that in addition to polycythemia, anemia or relative anemia were also important factors in the management of the hypoxic infant.[119,120] Around this time, the development of intensive care units together with the specialty of critical care medicine was initiated. Both of these factors improved the survival of extremely ill patients before and after palliative or reparative procedures. Critical care facilities have continued to improve during the last decade and many new pharmacologic agents have been introduced. A striking improvement in emergency transport facilities has occurred so that helicopter transport is now available in most tertiary referral centers. A team of skilled physicians and nurses can now be sent to outlying areas to provide rapid and stable transport of critically ill patients.

Despite these many advances in medical and surgical management, the modified natural history of the infant with transposition still included preoperative morbidity due to hypoxia and polycythema, or problems with pulmonary vascular obstructive disease. Postoperative problems included left ventricular outflow obstruction, right ventricular dysfunction, baffle obstruction, and arrhythmias. As a result of these ongoing problems, many centers began to look for a way to avoid these complications and thus entered the era of the arterial switch repair.

Prior to a discussion of the results of procedures available for palliation in the cardiac catheterization laboratory, or for surgical management, it is appropriate to consider some of the complications that have led to the desire to repair the infant with transposition of the great arteries as early in life as possible.

Hypoxia and Polycythemia

In the years prior to the repair of transposition during infancy, a post-balloon septostomy systemic arterial oxygen saturation of 60% or greater was considered to be an adequate result of palliative therapy.[97,98,106] This systemic desaturation did not seem to have a great effect on growth and development although these patients certainly did have less exercise capacity and stamina than their normal healthy siblings or peers. Some investigators have found that patients with transposition, even those with apparently adequate palliation, have delayed growth as compared to their normal peers. In addition, although most patients with transposition have normal intellectual and motor development, some do not.[121] However, it is extremely difficult to determine the specific etiology of developmental problems in patients with transposition who not only are cyanotic but also undergo multiple cardiovascular procedures. It is possible that this is related to the cyanosis. However, it may be related instead to the surgical procedures, to the timing of these procedures, or possibly even to the psychosocial abnormalities that are known to occur in this group of patients.

Polycythemia is a major physiologic consequence of the presence of hypoxemia. In general, patients with transposition and adequate palliation have an increased red blood cell count and a hemoglobin that is between 17 and 19 g/dL. This corresponds to a hematocrit of between 50 and 57%. When the hematocrit is in this range, the increased number of red blood cells is sufficient to provide adequate peripheral oxygen delivery while it is not so high as to produce the serious side effects of polycythemia. However, when the hematocrit is above 60% the viscosity of blood increases geometrically for each linear increase in the percent hematocrit. This tends to produce a substantial increase in viscosity especially when the hematocrit is over 65%.[122] This increased viscosity results in peripheral sludging of blood and places the patient at greater risk for having the neurological complications that will be described below. Another important complication of high hematocrit and high blood viscosity is the alteration of clotting factors that occurs in these patients.[123,124] When the hematocrit is 65% or higher, there is an alteration of the coagulation status with increased prothrombin time and low platelets, fibrinogen, and other coagulation factors. This most likely occurs as a result of a subclinical consumption coagulopathy.[124,125] Although this altered coagulation state is usually of little consequence, it is a serious problem for the patient who is about to undergo open heart surgery. Thus, when a polycythemic patient with a hematocrit over 60% is about to undergo surgical repair, it is important to check the patient's coagulation profile about a month prior to operation. If it is found to be abnormal, then phlebotomy and an exchange with a plasma substitute is recommended to be performed approximately a week to 10 days prior to operation. Reduction of the hematocrit below 60% serves to improve the cardiovascular status,[126] reduce peripheral sludging, and will improve the patient's coagulation status thus minimizing the risk of bleeding diathesis postoperatively.[127]

Neurologic Complications

Patients with transposition of the great arteries, especially those with marked polycythemia, may have a wide range of neurologic problems, some of which are readily reversible and others with permanent residua.[119,120] Headaches are a common complaint of patients with polycythemia especially when the hematocrit is over 65%. These are probably related to the sludging of blood in the capillary circulation of the brain and these symptoms are readily reversed following phlebotomy procedures. Delayed intellectual and/or motor development and seizures occur in patients with transposition of the great arteries.[121] It is possible that these problems are related to the profound systemic hypoxemia that many of these patients had during the neonatal period or early infancy.[128] However, it must be remembered that in transposition as in other patients with cyanotic congenital heart disease, there is a direct route from the systemic venous circulation to the systemic arterial circulation and thereby to the brain. Spontaneous intravascular thromboses, either arterial or venous, can occur in the presence of severe polycythemia. Thus, small intracerebral vessel thrombosis, or peripheral venous thrombosis with systemic arterial embolization, can occur in the absence of an apparent major clinical event and yet result in these neurologic abnormalities. In the same respect, these patients may have inadvertent systemic arterial embolization during one of their multiple cardiac catheterizations or surgical procedures. Cerebrovascular accidents, which are more severe and permanent neurological complications, may have the

same underlying mechanism. These are often temporally related to procedures although as many as 50% occur spontaneously.[129]

Although the majority of these complications are related to procedures or occur in polycythemic patients, anemia may also be a factor.[119,120] While a hemoglobin concentration of 12 to 14 g/dL is normal for a noncyanotic patient, this level of hemoglobin, or lower, is a significant relative anemia for a patient with transposition who is hypoxemic. It has been our experience and that of others that relative anemia in a cyanotic patient is as much a risk factor for cerebrovascular accident as is severe polycythemia. Thus, patients at either extreme, with a hemoglobin below 15 grams or above 20 and corresponding hematocrit below 45% or above 60%, are at risk for the development of neurologic complications especially during infectious illnesses. Careful attention therefore must be paid to and appropriate management instituted for not only polycythemia but also relative anemia. If a patient with transposition and hypoxemia is found to have a hemoglobin less than about 16 g/dL and a corresponding hematocrit of about 50%, supplemental oral iron therapy should be instituted to raise the hemoglobin and hematocrit to what is considered an appropriate level for that patient's degree of cyanosis and hypoxemia.

Pulmonary Vascular Obstructive Disease

Patients with other forms of cyanotic congenital heart disease generally have reduced pulmonary blood flow and therefore are not at risk for pulmonary vascular disease. Patients with transposition of the great arteries have increased pulmonary blood flow, yet have cyanosis as a result of poor mixing between the two separate parallel circulations. It has been well documented that patients with transposition and an additional shunt lesion, such as a ventricular septal defect or large patent ductus arteriosus, are at risk for developing this complication.[73–75] Furthermore, this problem occurs even in patients with transposition and an intact interventricular septum. It is possible that this predisposition to the development of pulmonary vascular disease in patients with transposition is somehow related to a combination of a number of factors. These include the large amount of pulmonary blood flow, the increased shear forces on the walls of the pulmonary arterioles caused by the polycythemia, the large additional systemic to pulmonary collateral flow seen in some patients, or some other unknown factor. In most cases where pulmonary vascular disease has occurred, the etiology is unclear. In the past, when repair of transposition was often delayed until the end of the first year of life or later, it was important to measure the pulmonary artery pressure in all patients with this abnormality at around 6 months of age. With the advent of surgery during infancy, concern about pulmonary hypertension now usually only remains in patients who have undergone banding of the pulmonary artery or who have not had repair of their anomaly by 6 months of age. Although it is uncommon today, there are some patients with transposition and a ventricular septal defect who have already developed pulmonary vascular disease for whom effective palliation can be achieved by performing an atrial baffle repair without closure of the ventricular septal defect.[130–132]

Catheter Septostomy—Results

Balloon atrial septostomy was the first interventional procedure used in the cardiac catheterization laboratory. It was extremely successful in providing immediate palliation for the patient with transposition of the great arteries. With widespread availability of balloon catheters by the late 1960s and early 1970s and the dissemination of information about the appropriate methods to be employed in performing this procedure, successful initial palliation was achieved in over 85% of patients.[90,97] Effective longterm palliation for as long as 2 or 3 years was possible for 65 to 75% of patients who underwent balloon atrial septostomy during infancy.[133] Until the development of blade atrial septostomy by Park in 1975[100] no other nonsurgical option was available for the approximately 25% of patients in whom balloon atrial septostomy was not effective either initially or subsequently during infancy. In an extensive collaborative study reported in 1982,[102] about 80% of this group of patients who required additional palliation by blade septostomy during infancy and childhood had an adequate result.

Despite the widespread use and unquestionable benefit of balloon and blade atrial septostomy, complications of these procedures have taken their toll. Most series describing the results of balloon septostomy from the 1960s and 1970s reported an occasional complication due to tears of myocardial or vascular structures, or injury to the mitral or tricuspid valve during the procedure. Today, with careful attention to detail, biplane fluoroscopic determination of catheter position and/or echocardiographic guidance, these complications of balloon atrial septostomy have largely been eliminated. Myocardial perforation or tear has also been reported in a few cases during blade septostomy.[102] These occurred during the early experience with this procedure and subsequent modifications of the blade catheter and careful use of the recommended procedures should minimize the likelihood of future occurrences. Major neurologic complications have occurred during or shortly following both balloon and blade septostomy procedures.[102,103,129] In the case of balloon septostomy, some of these were related to balloon rupture and embolization of balloon fragments. This problem has been largely eliminated due to improved materials and techniques of catheter design. In addition, careful evacuation of air from the balloon prior to catheter insertion and subsequent inflation in the patient, will minimize the possibility of air embolism should rupture of the balloon occur during septostomy.

Other causes of cerebrovascular accident occurring during or after cardiac catheterization and balloon or blade septostomy, include profound hypoxemia before or during the procedure, excessive blood loss, aspiration of air through a sheath into the venous system, or clot formation and systemic embolization. Profound hypoxemia is less of a problem today because of the use of prostaglandin E_1 in the neonatal period. Excessive blood loss due to tearing of femoral venous structures was a problem in the 1960s and early 1970s when catheters were inserted by the cutdown method. Blood loss was also a problem initially, using the percutaneous technique, since the internal diameter of the sheath required for balloon or blade insertion was much larger than the diameter of the catheter shaft. This not only resulted in the problems with excessive blood loss but also had the potential for allowing introduction of air through the sheath during the procedure. Today, most centers would insert these catheters by percutaneous technique wherever possible. The use of a sheath with a side port and a backbleeding control device is essential to prevent these complications.

Palliative Surgical Procedures

The era of surgical management of transposition of the great arteries began in 1950 with the description of closed atrial septectomy by Blalock and Hanlon[7] and pulmonary artery banding by Muller and Dammann.[109] Although the Blalock-Hanlon technique provided effective palliation for patients with transposition, especially those with an intact interventricular septum, the mortality from this procedure was high and ranged from a low of 20% to as high as 80%.[134–137] After the development of balloon septostomy, surgical septectomy was still used in patients in whom adequate palliation could not be achieved with the balloon catheter. The need for surgical palliation of transposition decreased considerably as more centers began to use profound hypothermia and circulatory arrest for repair of this lesion during infancy. Thus, by the early 1980s it was rare for a Blalock-Hanlon atrial septectomy to be performed in most institutions.

Pulmonary artery banding is used to reduce pulmonary blood flow in a patient wth transposition and a ventricular septal defect.[133] From 1950 through 1965 this was the only means of treatment of patients with this combination. Those who did not have this procedure either died or developed pulmonary vascular disease. Even during the decade following the description of the Mustard operation, repair was generally performed after 2 years of age. Thus, pulmonary artery banding was required during infancy for patients with an associated ventricular septal defect. In most patients, successful palliation was achieved with pulmonary artery banding alone or in combination with balloon septostomy or surgical atrial septectomy.[138] After it became possible to repair transposition of the great arteries during infancy, most centers preferred to perform a primary repair whenever possible rather than to perform pulmonary artery banding during infancy followed by repair at an older age.[79,139] Exceptions to this occurred in very small infants or in patients with associated multiple ventricular septal defects.

The arterial switch repair, described by Jatene in 1975, requires the left ventricle to function as the systemic ventricle postoperatively.[81] In order for this operation to be successful, the left ventricle needs to be ''prepared'' for systemic pressure.[140] This is not a problem in the neonatal period since the left ventricle has functioned against systemic pressure and resistance during fetal life. However, after 3 or 4 weeks of life, the left ventricle will no longer be able to function as the systemic ventricle unless it continues to face systemic pressure after the neonatal period. In patients with a ventricular septal defect and equal pressures in the right and left ventricle, an arterial switch procedure therefore is still possible later during infancy. In an infant, it is possible either to perform a pulmonary artery banding and consider an atrial baffle or arterial switch repair later during infancy or childhood, or to perform a primary repair early in infancy. In some centers pulmonary artery banding has also been used to ''prepare'' the left ventricle in patients with transposition and an intact interventricular septum who are beyond the neonatal period. In these patients, pulmonary artery banding is performed to raise the left ventricular pressure near to systemic level for a few months before arterial switch repair is performed.[141]

Systemic-to-Pulmonary Artery Anastomoses

The Blalock-Taussig anastomosis described in 1945,[107] or more recently its modified form using the Gore-Tex interposition graft between the subclavian and pulmonary arteries,[142] are the procedures of choice in infants with transposition and significant left ventricular outflow tract obstruction. In general, these are patients in the complex transposition category who have an associated ventricular septal defect and pulmonary stenosis. However, on occasion, a systemic-to-pulmonary artery anastomosis is effective even in a patient with transposition, an intact interventricular septum, and severe left ventricular outflow tract obstruction. Although other anastomoses, such as those described by Waterston,[110] Cooley,[111] and Potts,[108] have been used in the past, problems of pulmonary hypertension, kinking of the pulmonary arteries, and difficulties of takedown at the time of repair have made these anastomoses less favored than the previously mentioned subclavian artery procedures. In general, these procedures have been quite successful in providing effective longterm palliation for patients in the complex transposition category.

Atrial Baffle Procedures

A number of different types of partial and complete atrial redirection operations, including the Senning operation,[8] were suggested but had little success prior to the description of the atrial baffle repair by Mustard in 1964.[9] Subsequently, this technique was the only procedure used by most centers for the repair of transposition until the early 1980s when it became popular instead to use the Senning operation.[118] The goal of both the Mustard and the Senning atrial baffle procedures is to redirect the venous inflow to the heart so that the pulmonary venous drainage is channeled to the tricuspid valve and the systemic circulation, while the systemic venous drainage is channeled to the mitral valve and the pulmonary circulation. In the Mustard operation, an incision is made in the right atrium (Fig. 71–27A) and the atrial septum is then excised widely (Fig. 71–27B and C). A baffle of either autologous pericardium or synthetic material is used to partition the atrium. The baffle is sutured to the left side of the pulmonary veins and then around the vena caval orifices (Fig. 71–27D). This will direct the systemic venous inflow on the left side of the baffle and into the mitral valve. Pulmonary venous drainage will pass around the baffle and into the tricuspid valve. A patch is usually used to enlarge the new pulmonary venous atrium at the end of the procedure (Fig. 71–27E).

The Senning operation takes a different approach to provide similar partitioning. In contrast to the Mustard operation where the atrial septum is excised, the Senning procedure uses a flap of atrial septum to form part of the baffle (Fig. 71–28). After an initial atrial incision is made, (Fig. 71–28A) the atrial septum is detached with a U-shaped incision, along the anterior-superior margin (Fig. 71–28B). The flap of interatrial septum is sutured to the posterior left atrial wall so as to include the pulmonary veins behind this newly moved septal flap (Fig. 71–28C). If the flap is insufficient due to a large atrial septal defect, a patch of synthetic material is usually added. Then, another incision is made in the wall of the left atrium parallel to the initial right atrial incision but just to the left of the interatrial septum (Fig. 71–28C). The medial flap of atrial wall is then sutured to the interior of the atrium along the free margin of the previous incision in the atrial septum (Fig. 71–28D). This will serve to direct the systemic venous return to the left atrium. The remaining portion of right atrial wall is then pulled over this internalized flap and sutured to the posterior left atrium thus forming the new pulmonary venous atrium (Fig. 71–28E). An additional patch is frequently used to

enlarge this new pulmonary venous atrium. These multiple infoldings of tissue flaps appear to be quite complex and are difficult to visualize. This led to the abandoning of the Senning procedure in the mid 1960s in favor of the simpler Mustard operation. However, despite these apparent difficulties, our surgical colleagues now tell us that the Senning procedure is actually easier to perform in infants and small children.

In the years before the use of profound hypothermia and circulatory arrest, the Mustard procedure was generally performed between 1 and 3 years of age with over 80% survival in most centers.[72,76,138,143] When infant surgery became possible, success with atrial baffle procedures progressed even further and many of the preoperative problems associated with hypoxemia and polycythemia were reduced by early repair.[26,77,139,144] Today, in most centers, a survival rate of over 95% would be expected for atrial baffle repair of transposition during infancy, usually by the Senning operation.[145,146] In the late 1960s, many centers did not routinely perform cardiac catheterization on patients who had survived the Mustard operation, especially when they were clinically doing well. A few patients were noted to have clinically significant venous obstruction but most were felt to have an excellent result with no residual hemodynamic abnormalities. In the early 1970s, baffle obstruction was more frequently recognized as routine postoperative cardiac catheterizations were performed. It became apparent that about 10 to 20% of patients who underwent the Mustard operation had significant systemic venous obstruction postoperatively.[30,147–149] While some were severe enough to require reoperation, others were either not clinically apparent or the findings

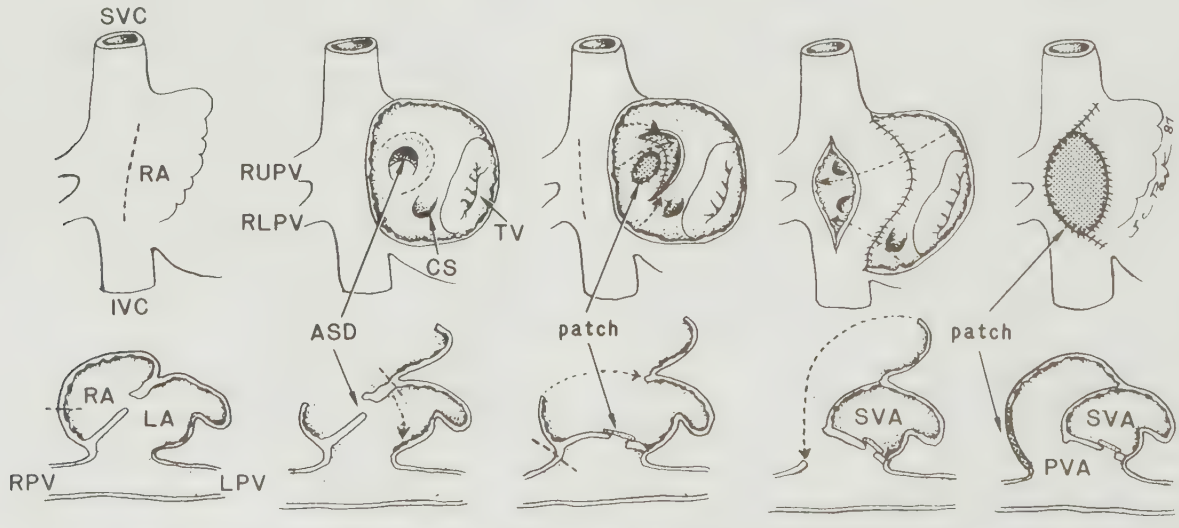

Fig. 71–28. Diagram illustrating the Senning operation (see text). Top: surgical view of the repair through the right atrium. Bottom: cross-section view of each sequence of the repair. See Fig. 71–27 for legend to abbreviations.

were subtle and often overlooked.[30,148] Pulmonary venous obstruction has been found less frequently, in about 5 to 10% of survivors, often occurring as a late complication.[148–151] These were commonly more severe degrees of obstruction that required reoperation. It was initially thought that these problems with venous obstruction were related to shrinkage of the pericardium used for the atrial baffle.[152] This led to the use of a variety of synthetic materials including Dacron and Gore-Tex as well as a variety of different shapes being recommended for the baffle to avoid these problems. As additional experience was gained with each of these methods and types of materials, it became obvious that most of the problems were related to the size and placement of the baffle rather than the material that was used. In the form in which the Mustard procedure finally evolved, most surgeons preferred to put in a large enough baffle to ensure an adequate opening across the superior and inferior vena caval inlet and enlarged the lateral wall of the right atrium with a patch to prevent obstruction in the new pulmonary venous atrium.

Atrial arrhythmias are another important problem in patients who have undergone a Mustard operation. It was common for patients to have sinus arrest with a junctional escape rhythm and episodes of supraventricular tachycardia in the early postoperative period. These abnormal findings usually resolved and these patients initially were then thought to be in sinus rhythm. In the early 1970s reports began to appear of atrial arrhythmias and sick sinus syndrome in patients who had undergone Mustard repair.[78,91] It was suggested by El-Said et al.[91] that these patients were not truly in sinus rhythm, and it quickly became apparent from this and other studies that direct damage to the sinus node and/or to the sinus node artery frequently occurred at the time of Mustard operation.[18,91] Longterm followup studies from our institution[80] and others[91–96] indicated that the percentage of atrial arrhythmias continued to increase in frequency with increasing length of postoperative followup. On the basis of these investigations, surgeons modified the operative technique to avoid cannulation in the area of the sinoatrial node and judiciously placed sutures in the high right atrial portion of the baffle to avoid injury to the sinus node artery along its expected course.[153] Particular attention was also paid to placement of sutures in the region between the coronary sinus and tricuspid valve to avoid damage to the atrioventricular node.

Lastly, the surgical technique was altered to avoid incision in the roof of the coronary sinus.[143,144] In the standard Mustard technique, the roof of the coronary sinus was incised back toward the left atrium for the purpose of including the unoxygenated coronary sinus drainage on the systemic venous side of the baffle. It was theorized that the removal of the atrial septum had destroyed the anterior and middle internodal pathways while the "unroofing" of the coronary sinus destroyed the remaining posterior internodal tract thereby producing the atrial arrhythmias seen postoperatively. Although there has been some discussion as to whether or not these internodal tracts exist either physiologically or anatomically, the decision was made for both the Mustard, and later the Senning operations, to leave the coronary sinus untouched and allow it to drain on the pulmonary venous side of the baffle. This results in slight systemic desaturation; however, this appears to be of little consequence. Unfortunately, all of these modifications mentioned above occurred over a short time period and it is impossible to determine whether this latter modification had any direct beneficial effect or was just temporally related to the benefits that resulted from the techniques that were designed to avoid injury to the sinoatrial node.

In the period around 1980, it seemed obvious that these modifications of the Mustard procedure had been successful. Junctional rhythm and supraventricular tachycardia were uncommon in the early postoperative period and pulmonary or systemic venous obstruction were much less commonly seen both in the early postoperative period and on late followup. Although there was not uniform agreement as to which material should be used for the atrial baffle, equally good results were obtained with either pericardium or synthetic materials. At about this time reports of success with the Senning operation began to appear.[118,154] Since this operation used the patient's native atrial tissue rather than nonviable material for the atrial baffle, its proponents suggested that the use of this technique would eliminate most of the postoperative problems that were found following the Mustard operation. On this basis, the Senning operation became the atrial baffle procedure of choice, in most centers, for the repair of transposition.[145,146,155–157] Initial results with this procedure were encouraging but it is difficult to determine whether the improvements in postoperative complications were as a result of factors inherent in the Senning procedure, or were as a result of experience that was gained in attempts to avoid these complications from the Mustard operation. In our own series of 45 patients who have had a Senning operation, systemic venous obstruction is uncommon. However, pulmonary venous obstruction occurs with a similar frequency as was found following the Mustard procedure. This is true even though a patch has been placed in the lateral wall of the right atrium to enlarge the new pulmonary venous atrium in an attempt to avoid the problem of pulmonary venous obstruction. In addition, junctional rhythm was present intraoperatively or in the early postoperative period in over 60% of our series. Although almost all patients were in sinus rhythm by the time of discharge, a few have had problems with atrial flutter, 30% have prolonged sinus node recovery time on postoperative cardiac catheterization and junctional rhythm is present in two of the earliest patients in the series who are now 7 years postoperative. Similar findings have also been reported by others.[158,159] It should be emphasized that problems with venous obstruction, atrial arrhythmias, and sinus node dysfunction were not reported until 5 or 6 years after the beginning of the Mustard operation era. This is particularly true of the electrophysiologic abnormalities since many patients exhibited these problems only on late followup. Thus, although the Senning operation is easier to perform on the small infant and at this point appears to have a lower frequency of complications as compared to the Mustard operation, only longterm followup over the next decade will provide conclusive proof that it is the superior of the two atrial baffle procedures.

Tricuspid valve incompetence has been reported to occur following atrial baffle operations. It is possible that this is caused by the inability of the tricuspid valve to function as the systemic atrioventricular valve over a long period of time in some cases. However, in the majority of patients, tricuspid incompetence is found early postoperatively and is probably in some way related to the operative procedures. Tynan et al.[160] suggested that this abnormality was related to arrhythmias developing as a result of surgery. However, in our series,[30] and in others,[79,148,149] tricuspid incompetence was most often seen in patients who had closure of

a ventricular septal defect through the tricuspid valve. This suggests injury to the valve structure or its support apparatus at the time of operation. Fortunately, postoperative tricuspid valve incompetence occurs in less than 5% of patients and is usually mild.[141] However, since this valve must tolerate systemic pressure for many years, even a mild degree of incompetence may become a significant and potentialy lethal complication over the long term.

Another major problem that is yet unsolved is the concern about the ability of the right ventricle to function as the systemic ventricle over a patient's lifetime. Many investigators have studied systemic right ventricular function in patients following the Mustard operation and these studies conclude that ventricular function is generally below normal despite the fact that these patients seem to be well and appear to be able to function normally.[161–164] However, some of these conclusions may be misleading. The normal values used to assess function of a systemic left ventricle may not be directly applicable to the systemic right ventricle. In addition, many patients who clearly have systemic ventricular dysfunction as compared to their postoperative peers with transposition had this abnormality preoperatively, or on the basis of problems encountered during the perioperative period. This is supported by Graham et al.[165] who found improved right ventricular function in a group of patients who underwent a Senning procedure as compared to a group of patients who had a Mustard operation. This improved right ventricular performance may be due to a younger age at operation, better preoperative myocardial function, or improved intraoperative myocardial protection.[165] It appears that patients who have good postoperative systemic ventricular function generally maintain this good function over a long period of time. Since many of the patients who were the first to undergo atrial baffle repair are currently only entering their third postoperative decade, the question of the ability of the right ventricle to function as the systemic ventricle for a patient's lifetime remains to be answered.

Arterial Switch Repair

The concerns about longterm systemic ventricular function, along with problems of baffle obstruction and electrophysiologic abnormalities that are present with both types of atrial baffle repair, led surgeons to reconsider the possibility of an arterial switch repair. It has always been technically relatively easy to divide the transposed great arteries and reanastomose the vessels so as to provide a concordant ventriculoarterial connection. The problem, of course, lies in the fact that the coronary arteries arise from the sinuses of the semilunar valve that is connected to the right ventricle. Since this becomes the pulmonary valve after an arterial switch repair, the coronary arteries would be perfused with low pressure, unoxygenated systemic venous blood and this is invariably fatal. In the past, a wide variety of procedures for reconnecting one or both coronary arteries to the aorta were suggested or attempted. These procedures were all unsuccessful until the report by Jatene in 1975[81] of survival following an arterial switch repair that included transplantation of both coronary arteries into the reconnected aorta. This technique included the removal of the coronary arteries from the base of the aorta by excision of a cuff of aorta about the coronary orifice and anastomosis of this cuff to two similar size openings made in the base of the pulmonary artery where it arises from the left ventricle (Fig. 71–29A and B). The aorta is then reconnected to the proximal stump of the pulmonary artery while the pulmonary artery is connected to the proximal stump of the aorta (Fig. 71–29C).

The arterial switch repair initially was met with great enthusiasm but, unfortunately, the initial experience with this procedure in most centers was discouraging. The mortality was generally over 70%[166] and most centers returned to using an atrial baffle procedure for repair of transposition. However, a few centers continued to perform arterial switch repair and reported a dramatic increase in survival as more procedures were performed.[141,166,167] This convinced some additional centers to again attempt to perform the arterial switch operation. It has become apparent that there is a "learning curve" for the surgical team that performs this operation.[166,168] As more centers begin to perform the arterial switch repair, the mortality due to this "learning curve" can be minimized by consultation and close collaboration with those centers that have already been successful in avoiding the problems and pitfalls that are associated with this initial high mortality.

The ability of the left ventricle to function against systemic pressure and resistance is an essential factor for a successful arterial switch repair. In the patient with transposition of the great arteries and an intact interventricular septum, the left ventricular pressure usually falls to below half systemic level within the first week of life and loses this ability to function against systemic pressure by about the third week of age. In the patient with left ventricular outflow tract obstruction, systemic pressure may be present in the left ventricle after the first month of life. However, an arterial switch repair cannot be performed since this will result in obstruction to outflow in the systemic ventricle postoperatively. In transposition with a large patent ductus arteriosus or with a ventricular septal defect, pulmonary hypertension may persist, and the left ventricle will thus retain its ability to function as the systemic ventricle. In these patients, in contrast to the patient with an intact interventricular septum and low left ventricular pressure, the arterial switch repair can be delayed until a few months of age.[167,169] However, early operation may be required because of congestive heart failure or concerns about pulmonary vascular disease. If early repair is not possible and banding of the pulmonary artery is performed in the patient with a ventricular septal defect, congestive heart failure and concerns about pulmonary hypertension can be reduced or eliminated while left ventricular pressure remains at systemic level.[167] An arterial switch repair can then be performed later during infancy, or even during childhood, when it may be easier to attempt to close the ventricular septal defect. As was previously discussed in the section on palliative procedures, pulmonary artery banding also has been used in some centers to "prepare" the left ventricle in transposition of the great arteries with an intact interventricular septum, when the patient is beyond the neonatal period.[141]

There are a number of areas of concern in patients who have survived an arterial switch repair. The maintenance of normal coronary artery blood flow is of major importance. In general, it is likely that those patients with compromise of the coronary circulation do not survive operation. However, we have had occasion to perform a heart transplant on an 18-month-old patient who underwent an arterial switch at another institution and sustained a severe myocardial infarction. In some instances, myocardial ischemia may result from kinking of the coronary artery or external compression by the surrounding tissue or the newly connected pulmonary artery.[167] If these problems are recognized in the early

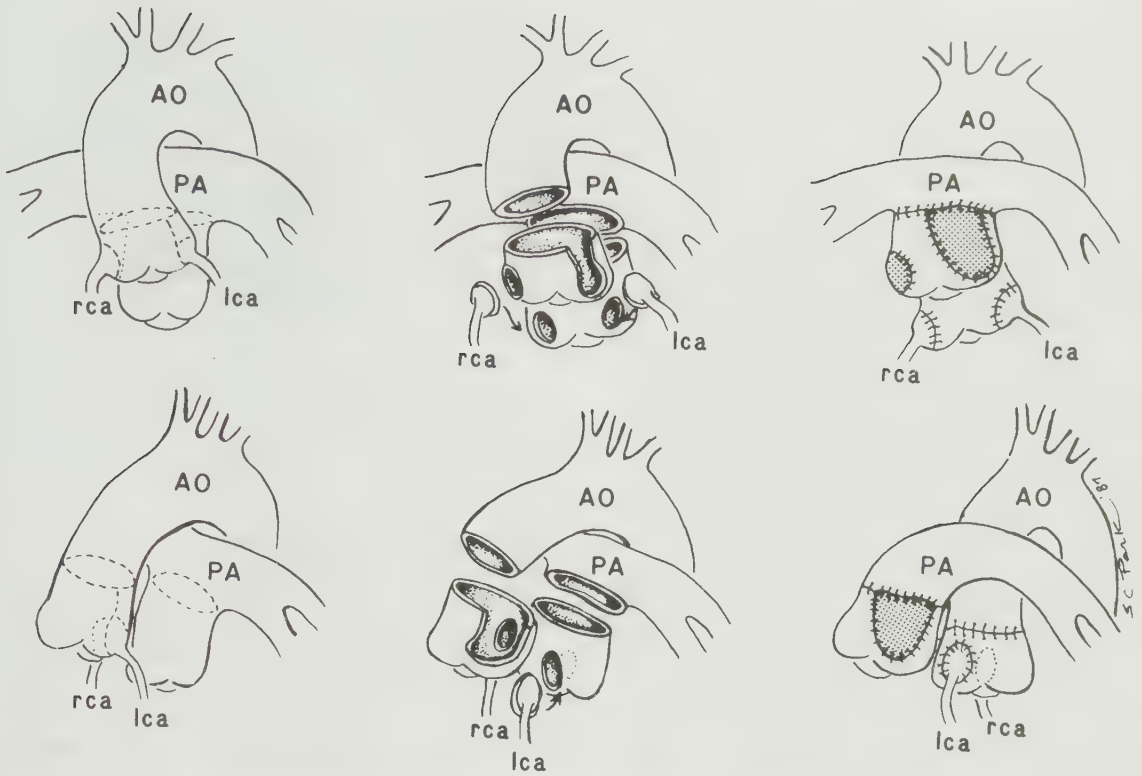

Fig. 71–29. Diagram illustrating the arterial switch repair (see text). Top: frontal view. Bottom: sagittal view. Ao = aorta, PA = pulmonary artery, lca = left coronary artery, rca = right coronary artery.

postoperative period then reoperation might be attempted. Another concern is the site of the anastomosis for reconnection of the great arteries. The reported difficulties usually have been with pulmonary artery stenosis and some patients have required reoperation to correct this problem.[166,167] At the time of primary repair, a patch of synthetic material is generally used to enlarge the pulmonary artery at the site of anastomosis. In addition, patches are also placed over the openings that result from the removal of the coronary arteries with the surrounding cuff of what was formerly the wall of the aorta. Some cases of stenosis at the site of the aortic anastomosis have also been reported but these are generally mild and have rarely required reoperation.

The long-term results of patients who have undergone an arterial switch repair for transposition of the great arteries are still unknown. Even though these above problems may not be present postoperatively in an infant who has undergone arterial switch repair in the first few weeks of life, there is still concern about growth of the anastomotic sites, or about possible compromise of transplanted coronary arteries as the patient grows to adulthood. It is only with time and additional experience that the question of whether an atrial baffle procedure or the arterial switch repair is preferable for the surgical management of the patient with transposition of the great arteries.

Rastelli Operation

The various procedures that have been described in this chapter have rarely been used successfully in the management of the patient with transposition of the great arteries, a ventricular septal defect and severe subpulmonic stenosis (complex transposition) (Fig. 71–30A). Although it is possible to close the ventricular septal defect in these patients, it is usually not possible adequately to relieve the muscular subpulmonic left ventricular outflow tract obstruction. As a result, most patients died and the few that did survive still had residual severe left ventricular outflow obstruction. In 1969 Rastelli et al.[113] described a procedure to repair complex transposition in which no attempt is made to resect the subpulmonic left ventricular outflow obstruction. An incision is made in the right ventricle and a patch is placed between the inferior border of the ventricular septal defect and to the right side of the outflow to the aorta (Fig. 71–30B). The pulmonary artery is oversewn and thus the outflow of the left ventricle is directed through the ventricular septal defect and out into the aorta. If it is felt that the ventricular septal defect will be inadequate to handle the systemic blood flow without obstruction, then the defect is enlarged prior to placement of the patch.[170] After the defect has been closed, one end of a conduit is connected to the incision in the right ventricle and its distal end is anastomosed to the pulmonary artery (Fig. 71–30C). The result of this operation is that the oxygenated, left ventricular blood is expelled into the aorta while the unoxygenated systemic venous return is ejected from the right ventricle through the conduit and into the pulmonary artery.

In general, a valved conduit has been used in the Rastelli procedure. Initially, a homograft aorta with its aortic valve and the anterior leaflet of the mitral valve still attached, was used. Most centers in England continue to use the homograft aorta with considerable success.[171,172] In the United States, problems of homograft calcification[173] and homograft availability led to the use of

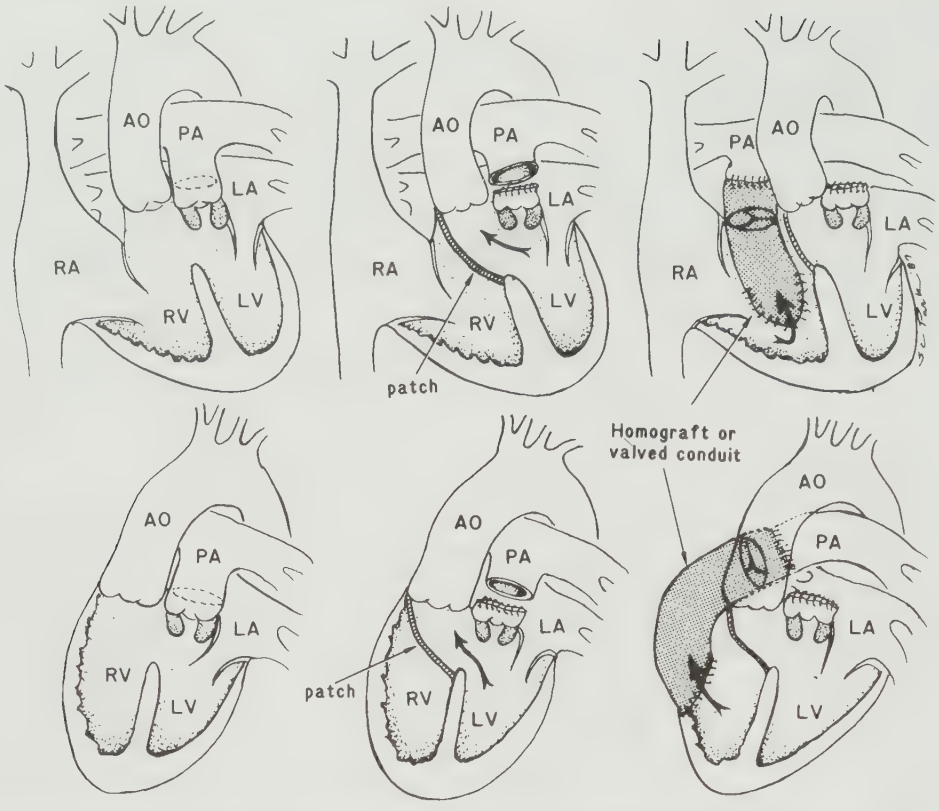

Fig. 71–30. Diagram illustrating the Rastelli operation (see text). Top: frontal view. Bottom: sagittal view. Ao = aorta, PA = pulmonary artery, LA = left atrium, RA = right atrium, LV = left ventricle, RV = right ventricle.

conduits of synthetic material that contained a porcine heterograft aortic valve. These conduits were used successfully and resulted in a better than 75% survival rate for the repair of patients with complex transposition.[170,174,175] Unfortunately, these heterograft conduits did not withstand the test of time and stenosis often occurred either due to an extensive, thickened endothelial lining and/or severe fibrosis and calcification of the heterograft porcine valve.[176] In most cases with significant obstruction it was necessary to remove the heterograft valve conduit and this was usually replaced successfully with a nonvalved conduit also of synthetic material.[174,177] In recent years, many centers have begun successfully to use a conduit of homograft pulmonary artery containing the pulmonary valve. These are freeze-dried and are available commercially in a wide variety of sizes. The longterm fate of these conduits is still unknown.

Other problems that have occurred following a Rastelli procedure for complex transposition include residual ventricular septal defects and pulmonary artery stenosis. An unrecognized defect, especially in the apical region of the muscular septum may be found postoperatively. However, this has become much less common as a result of preoperative evaluation with two-dimensional and Doppler echocardiography and careful high-quality angiocardiography in axial projections. Fortunately, when an anatomic defect is not a result of incomplete surgical closure and is newly recognized postoperatively, it is generally small and is of little clinical importance. On the other hand, it is important to assess the physiologic consequences of any residual ventricular septal defect of significant size. If there is more than twice normal pulmonary blood flow as a result of the defect, especially if the pulmonary artery pressure is also elevated, then the patient might be at risk for the development of pulmonary vascular disease and reoperation for closure of the defect would have to be considered. Abnormal postoperative ventricular function would be another indication for considering closure of a residual defect with a moderate shunt, even in the absence of pulmonary hypertension, since the increased volume load might further stress or compromise the ventricle.

Right ventricular hypertension may be caused by pulmonary artery stenosis.[178] This problem is more commonly found postoperatively in the patient with complex transposition when severe pulmonary stenosis or pulmonary atresia with resultant hypoplasia of the pulmonary artery tree is present preoperatively. If stenosis is found proximally, either at the right ventricular side of the conduit anastomosis, in the conduit itself, or at a proximal site of pulmonary artery anastomosis, then reoperation might successfully relieve the gradient. Unfortunately, it is often the case that the areas of stenosis are at a distal anastomosis between the conduit and small pulmonary arteries and these are usually not amenable to re-operation. In patients with tetralogy of Fallot, it has been suggested that preoperative measurement of the size of the pulmonary arteries angiographically is predictive of the postoperative right ventricular pressure and may be valuable in selecting patients for operation.[179] This formula may also be useful in patients with complex transposition and pulmonary artery stenosis. This technique is discussed in greater detail in the section on surgical management in Chapter 63 on tetralogy of Fallot.

Lastly, patients who have undergone repair of complex transposition with a Rastelli procedure may be at similar risk for the

development of postoperative atrioventricular conduction abnormalities and ventricular arrhythmias as are patients who have undergone repair of tetralogy of Fallot.[180,181] In both procedures, a right ventriculotomy is performed and there is patch closure of the ventricular septal defect. Although removal of infundibular muscle in the right ventricular outflow tract is only performed in repair of tetralogy, patients seem to be at similar risk from both procedures for the development of arrhythmias postoperatively. Thus, patients who have undergone Rastelli repair for complex transposition should have careful postoperative followup including hemodynamic and angiographic assessment, 24-hour ambulatory monitoring and stress exercise testing. It has been suggested that ventricular arrhythmias in the presence of right ventricular hypertension following repair of tetralogy of Fallot puts the patient at greater risk for sudden death. It is likely that patients who have undergone a Rastelli procedure are at similar risk in the presence of the same circumstances, however, this has not been firmly established.

SPECULATION ABOUT THE FUTURE

As we approach the twenty-fifth anniversary of the Mustard repair and of balloon septostomy, the management of the infant with transposition of the great arteries still varies greatly from center to center. The longterm outlook and longevity of patients who have undergone atrial baffle repair is still in doubt as a result of problems with arrhythmias and the question of the ability of the right ventricle to function as the systemic ventricle for an entire lifetime. The arterial switch repair seems to be an attractive alternative with the hope of eliminating these problems and concerns of repair using atrial baffle techniques. On the other hand, longterm followup is yet unavailable in these patients and problems with arterial anastomoses or the reimplanted coronary arteries are potential areas of future concern. The initially high surgical mortality has been reduced in those centers continuing to perform arterial switch repairs. However, the survival rate for this procedure is approaching but still does not match that of atrial baffle repair. In view of the potential great longterm benefits, the question arises should all centers now be performing the arterial switch repair? On the other hand, since there is a high mortality with the initial series of procedures in any given center, should the arterial switch be done in only a select number of centers? Although all of these questions remain to be answered, the last 25 years have brought life and hope to countless numbers of patients with a previously fatal abnormality. Hopefully, this progress will continue to take place over the next 25 years as well.

CHAPTER 72

Double-Outlet Ventricles

Michael J Silka

The concept of the double-outlet ventricle refers to a specific type of ventriculoarterial connection, in which both great arteries arise primarily from one ventricle.[1] The diagnosis of double-outlet right ventricle (DORV) applies when all of one and more than 50% of the other great artery arise from the morphologic right ventricle.[2,3] By similar convention, double-outlet left ventricle (DOLV) is diagnosed when both great arteries arise entirely, or predominantly, above the morphologic left ventricle.[4,5] Although the preceding definitions are conceptually simple, abnormal ventriculoarterial (VA) alignments remain difficult to characterize and categorize precisely, and continue to be the source of considerable controversy.[6] The concept of the double-outlet right or left ventricle refers only to a specific ventriculoarterial connection; considerable variations due to associated cardiac malformations and segmental connections must be considered separately. These anomalies, however, can be grouped in such a way as to provide significant physiologic and surgical information.[7] As DORV has a clearly established anatomic and embryologic basis, and is of much greater frequency than DOLV, it will be the primary emphasis of this chapter.[8,9]

DORV refers to a diverse group of congenital heart defects, with the common feature of origin of both great arteries primarily from the morphologic right ventricle. Identification of this type of ventriculoarterial connection does not specify the associated physiology, which may simulate that of a large ventricular septal defect, tetralogy of Fallot, or transposition of the great arteries. DORV is a rare defect, representing approximately 1.5% of recognized congenital heart disease.[10]

Because of the anatomic subsets of this defect, and association with other congenital heart defects, marked differences in medical and surgical prognosis exist within this group.[11] Recent advances in echocardiography and cardiac catheterization have clarified the variable pathology of this lesion, and provide the basis for the current definition of DORV.

Historically, a number of terms have been used for this malformation, including the Taussig–Bing complex,[12] partial transposition,[13] origin of both great vessels from the right ventricle,[9] and double-outlet right ventricle.[13] The initial definitions of DORV required that both great arteries arise completely from the right ventricle, with no fibrous mitral-semilunar continuity. Improved understanding of surgical and pathologic anatomy has resulted in the recognition that DORV represents a continuum of congenital heart defects, extending from ventricular septal defect with marked aortic override, followed by classic origin of both great vessels from the right ventricle, proceeding next to the Taussig–Bing complex, and finally transposition of the great arteries with pulmonary override of the ventricular septal defect. Thus, we define DORV in accordance with the classic study of Lev and colleagues: "Double-outlet right ventricle is an anomaly in which two cusps and part of the third of both semilunar valves arise from the right ventricle."[2] We recognize that other criteria for DORV have been offered; however, a diagnosis predicated on a specified amount of mitral-semilunar discontinuity or the requirement of absolute arterial override is inconsistent with the recognized spectrum of ventriculoarterial connections.[14] A descriptive, segmental approach,[15] of which double-outlet right ventricle is one component, will provide accurate anatomic and clinical definition.

ANATOMIC CONSIDERATIONS

As DORV refers to a specific type of ventriculoarterial connection, further classification is required, based on the presence and type of associated congenital heart defects and segmental connections. For this chapter, DORV will be restricted to anatomy in which there are two ventricles, and in which a ventricular septal defect is usually present and provides the only outlet for the left ventricle. The anatomic description of DORV requires three basic considerations: 1) the relationship of the great arteries; 2) the morphology of the ventricles and their outflow tracts; and 3) the presence of associated congenital cardiac defects. To describe these features, we will use the anatomic nomenclature proposed by Anderson et al.,[16] while recognizing that this terminology is not universal.

Any muscular structure that separates a semilunar valve from an atrioventricular valve will be defined as the ventriculoinfundibular fold. In the usual setting of DORV, this is the structure responsible for mitral-semilunar disontinuity. The size of this structure is variable, and determines the distance between the ventricular septal defect and the semilunar valve. This structure has also been termed the second parietal band[17] (Fig. 72–1).

The trabecula septomarginalis refers to the extensive septal trabeculation of the right ventricle. Superiorly, the trabecula septomarginalis divides to form two limbs, with the outlet septum fusing with the muscular septum at this bifurcation in the normal right ventricle. In most forms of DORV, however, the ventricular septal defect is cradled between these two limbs of the trabecula septomarginalis, and there is associated deviation of the outlet septum. This is the predicted location of the ventricular septal defect in DORV whether the ventricular septal defect is subaortic, subpulmonic, or doubly committed. The variable relation of the ventricular septal defect to the great arteries depends on the plane and extent of the outlet septum, and the relation of the great arteries.

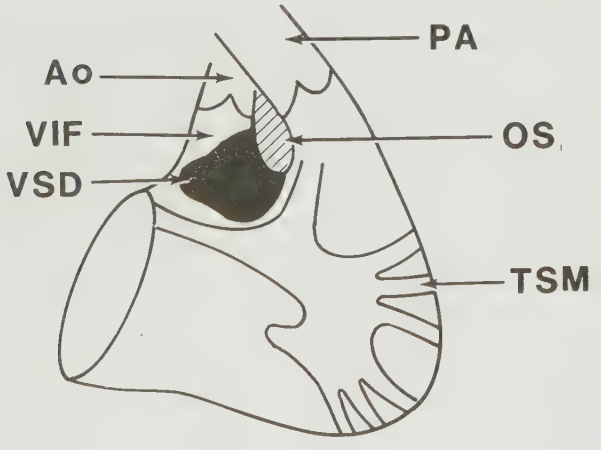

Fig. 72–1. Morphologic aspects of the double-outlet right ventricle with normally related great arteries. The right ventricle is illustrated as if the anterior free wall has been removed. The following structures are emphasized: 1) The ventriculoinfundibular fold (VIF), separating the atrioventricular and semilunar valves; 2) the trabeculaseptomarginalis (TSM) with the ventricular septal defect (VSD) cradled between the two limbs; and 3) the outlet septum (OS), separating the aorta (Ao) and pulmonary artery (PA).

Thus, the location of the ventricular septal defect in DORV is not random. The exception to this rule of location is the noncommitted ventricular septal defect, in which the defect is either apical trabecular, or membranous with inlet extension.[18]

The outlet (or infundibular) septum refers to the muscular division between the subaortic and subpulmonic outflow tracts. Also referred to as the conal septum or first parietal band,[17] the orientation and extension of this structure relative to the ventricular septal defect is variable. In DORV, the long axis of the outlet septum is directed toward the right ventricle, deviated from the plane of the muscular septum.

Using this terminology, DORV may be categorized into major subgroups based on the relation of the great arteries and consideration of location of the ventricular septal defect, with subsequent consideration of the presence or absence of associated cardiac anomalies.

Relations of the Great Arteries in Double-Outlet Right Ventricle

Three basic relations of the great arteries in association with DORV are recognized. The most frequent is a normal relation, with the aortic annulus posterior and to the right of the pulmonary annulus, with a subsequent spiral course of the great arteries. The second common relation is the aorta to the right of the pulmonary trunk, with a subsequent parallel course (side by side) of the great arteries. A third, and much less frequent form of DORV connection occurs with the aorta anterior and to the left of the pulmonary trunk (Fig. 72–2). Piccoli et al. have proposed classifying the forms of DORV according to the relation of the great arteries which is predictive of the anatomy of the associated ventricular septal defect.[19] This is of paramount importance, as the relation of the ventricular septal defect to the aorta will largely determine surgical alternatives.

Double-Outlet Right Ventricle with Normally Related Great Arteries

In this subtype of DORV, the aorta is posterior and to the right of the pulmonary artery. This resembles the arterial relation seen in the normal heart or in tetralogy of Fallot. Almost without exception, the finding of relatively normally related great vessels in DORV defines the ventricular septal defect as related to the sub-

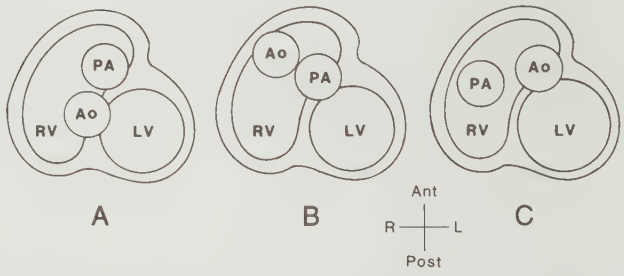

Fig. 72–2. Short axial view of the types of semilunar valve relations in double-outlet right ventricle. The aorta annulus (Ao) may be related to the ventricular septal defect either when posterior and right, or anterior and left (A and C). However, an anterior and rightward position of the aorta (B) is associated with a subpulmonic position of the ventricular septal defect.

aortic outflow tract. The proximity of the aortic valve to the ventricular septal defect will be determined by the dimensions of the ventriculoinfundibular fold. The associated absence or presence of pulmonic and subpulmonic stenosis will determine the magnitude of pulmonary blood flow and clinical presentation (Fig. 72–1). Rarely, the ventricular septal defect will be doubly committed or noncommitted.

The differentiation of DORV from tetralogy of Fallot is controversial in this setting.[2,20] Edwards has emphasized that DORV defines a type of ventriculoarterial connection, while tetralogy of Fallot refers to a specific infundibular septal malalignment.[6] The two terms are distinct, but not mutually exclusive. Tetralogy of Fallot with extreme aortic override represents one point in the spectrum of the diverse congenital heart defects grouped as DORV (Fig. 72–3).

Double-Outlet Right Ventricle with Parallel Great Arteries and Aorta to the Right

A significant difference in the alignment of the semilunar valves is anticipated when the great arteries are of a more or less parallel course, with a rightward and anterior origin of the aorta. In the continuum of DORV, this arterial relation will identify the left-sided pulmonary trunk as adjacent to the ventricular septal defect, within the limbs of the trabecula septomarginalis. The fusion of a well-formed outlet septum with the posterior limb of the ventriculoinfundibular fold confines the defect to a subpulmonary position (Fig. 72–4). This is in contrast with the subaortic defect, in which the infundibular septum inserts into the superior (anterior) limb of the trabecula septomarginalis. In either arterial relation, hypoplasia of the outlet septum results in a doubly committed ventricular septal defect.

The Taussig–Bing malformation is properly considered within the context of side-by-side great artery relations with an associated juxtapulmonary (supracristal) ventricular septal defect. Exact definition of the original heart described by Taussig and Bing is controversial, depending on consideration of the commitment of the pulmonary artery to the right or left ventricle.[21,22] The presence of a bilateral infundibulum is considered by some to be requisite to the strict definition of the Taussig–Bing heart,[23] while others dispute the significance.[2,3]

With further dextrorotation of the aorta, the ventricular septal defect remains closely related to the posterior pulmonary trunk. However, the defect now is subcristal in location, not as superior as noted in the classic Taussig–Bing malformation. It has been proposed that all cases of juxtapulmonary ventricular septal defect with malalignment of the infundibular septum be classified as the "Taussig–Bing" malformation due to common morphologic features that determine the surgical options.[24] DORV with d-transposition may more adequately describe the anatomy and physiology of this lesion.

Double-Outlet Right Ventricle with Aorta Anterior and Left

A much less frequent type of DORV connection is an anterior and leftward origin of the aorta with a subsequent parallel course of the great arteries. The aortic position approximates that identified in "corrected" transposition. Although this great artery re-

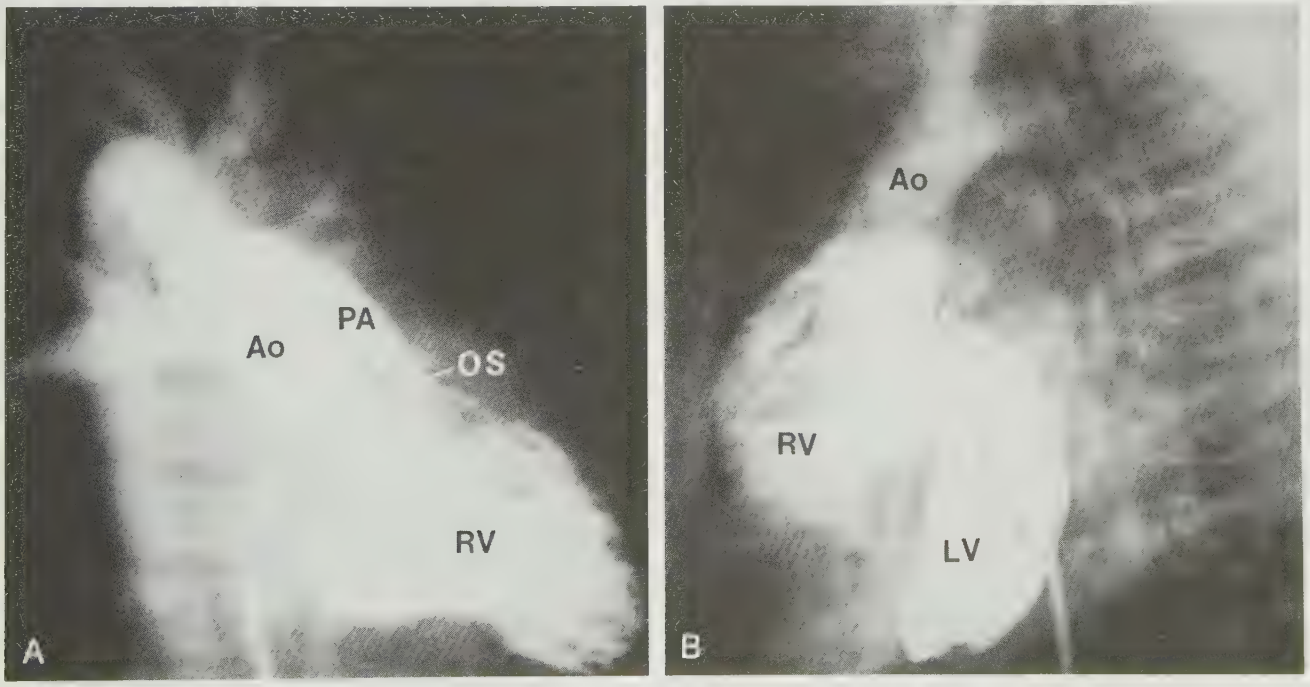

Fig. 72–3. Double-outlet right ventricle with normally related great vessels and severe subvalvar and valvar pulmonic stenosis. A) Frontal view right ventricular (RV) angiogram demonstrating severe anterior displacement of the outlet septum (OS), and a right aortic arch. B) Left ventriculogram (LV) in the left anterior oblique projection. The LV is relatively hypoplastic, and the aorta (Ao) is committed to the anterior RV, in distinction to overriding the VSD as in classic tetralogy of Fallot.

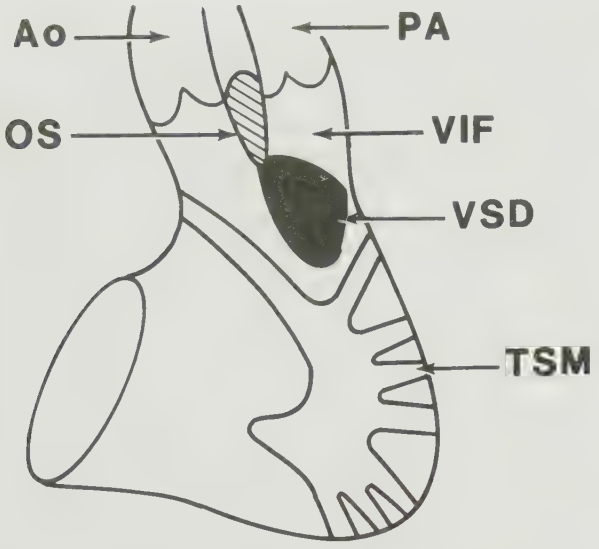

Fig. 72–4. Double-outlet right ventricle with side-by-side great arteries and subpulmonic ventricular septal defect. The outlet septum (OS) is related to the posterior (inferior) limb of the trabecula septomarginalis (TSM), with the ventricular septal defect related to the posterior pulmonary annulus. Attenuation of the ventriculoinfundibular fold (VIF) results in a juxtapulmonary ventricular septal defect, initially described as the Taussig–Bing anomaly.

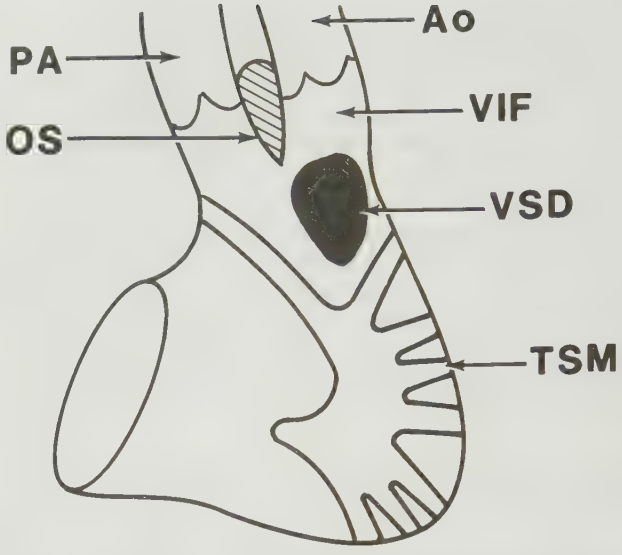

Fig. 72–5. An anterior and leftward position of the aortic annulus is associated with insertion of the outlet septum posterior to the superior limb of the trabecula septomarginalis (TSM). This position of the ventricular septal defect is similar to that when the great arteries are side by side and the ventricular septal defect is subpulmonic. However, differing degrees of rotation and extension of the outlet septum result in significant variability in the outflow anatomy of this defect.

lation is most frequently associated with a subaortic ventricular septal defect, the somewhat variable aortic position in this setting may result in a significant alteration in the morphology of the ventricular septal defect. The infundibular septum inserts posterior to the superior limb of the trabecula septomarginalis, so that the ventricular septal defect resembles that seen in the subpulmonary position when the aorta is right sided (Fig. 72–5). When the defect is doubly committed, both great arteries may override the ventricular septal defect. Brandt et al., have termed this "double-outlet both ventricles,"[25] extending the continuum of the double-outlet ventricles toward a double-outlet left ventricle.

The Ventricular Septal Defect in Double-Outlet Right Ventricle

The relation of the great arteries defines, in part, the location of the ventricular septal defect in DORV, based on the insertion of the outlet septum. The inferior margins of the ventricular septal defect are the two limbs of the trabecula septomarginalis, except in the noncommitted ventricular septal defect. In spite of these constants, variability in the size of the ventricular septal defect will occur due to the morphology of the ventriculoinfundibular fold and the degree of extension of the infundibular septum. Four types of interventricular communications are identified in DORV:

1. Subaortic ventricular septal defect: This is the defect location in the setting of normally related great vessels, and most frequently when the aorta is anterior and leftward. The ventriculoinfundibular fold is interposed between the ventricular septal defect and the aortic valve, resulting in a muscular border around the entire defect. Attenuation of the ventriculoinfundibular fold would result in a perimembranous ventricular septal defect, with aortic override, while associated cephalad deviation of the infundibular septum would result in tetralogy of Fallot. The various forms of pulmonary stenosis are frequently associated with DORV and subaortic ventricular septal defect due to deviation of the infundibular septum.
2. Subpulmonic ventricular septal defect: This is the defect location when the aorta annulus is to the right and/or anterior to the pulmonary annulus. This defect may be either muscular or perimembranous, predicated on the extent of the ventriculoinfundibular fold. Left-sided obstructive cardiac lesions most frequently occur in association with this anatomy.[26]
3. Doubly committed defects: Absence or marked hypoplasia of the infundibular septum will result in override of the ventricular septal defect by both great arteries. When totally absent, both great arteries may override the ventricular septum.
4. Noncommitted defects: An apical trabecular or membranous-inlet ventricular septal defect is remote from both great arteries in DORV, and thus termed noncommitted. Atrioventricular septal defects are the most frequent type of VSD associated with this type of DORV.[27]

Varying degrees of left ventricular outflow obstruction may result from a restrictive ventricular septal defect or an intact ventricular septum. As the ventricular septal defect provides the outflow tract for the left ventricle in DORV, it has been termed "physiologically advantageous."[28] The actual incidence of a restrictive ventricular septal defect in DORV (i.e., systolic pressure gradient between the left and right ventricle) has been reported to be 3%.[29,30] However, more recent studies using two-dimensional echocardiography have indicated that a small ventricular septal

defect, requiring enlargement at the time of surgery, may be much more common than initially reported.[31] Recognition of a restrictive defect is mandatory before surgical repair is attempted, as the interventricular communication can be safely enlarged superiorly[32] (Fig. 72–6).

Isolated cases of spontaneous closure of the ventricular septal defect in the setting of DORV have been reported. Most frequently they have been associated with hypoplasia of the mitral valve apparatus or left ventricle,[33] although instances of ventricular septal defect closure with previously normal left ventricular anatomy have been reported.[34,35] Survival is based on left-to-right atrial shunting in this setting.

EMBRYOLOGY

Double-outlet right ventricle represents a relatively primitive embryologic defect within the group of bulboventricular malformations. At Streeter horizon 15, the primitive truncus completely overrides the primitive right ventricle, with the future aortic valve to the right of the future pulmonic valve. At this stage of embryogenesis, three events appear necessary to result in the production of normal ventricular outflow tracts: 1) clockwise inversion of the distal conus, which results in a posterior location of the future aortic valve; 2) leftward shift of the conoventricular junction, committing the aortic conus to the left ventricle; and 3) subsequent differential absorption of the subaortic conus resulting in mitral-aortic continuity.[36] Goor and Edwards[37] have proposed that DORV be included within the "spectrum of transposition complexes," based on a common failure of conal inversion. Failure of leftward shift of the primitive conus would result in persistence of origin of both great vessels from the right ventricle, while subsequent differential conal absorption in the absence of "inversion" would result in transposition of the great arteries. Anderson et al. expanded these concepts to a spectrum of bulboventricular malformations extending from tetralogy of Fallot to transposition of the great arteries, with DORV representing the intermediate expression of basic defects of conal absorption and rotation. Emphasis was also placed on the orientation of the anterior muscular septum in defining the relationship of the great arteries of the ventricular septal defect.[38] The intermediate morphologic forms of DORV with transposition or DORV with tetralogy of Fallot are determined by the orientation of the conal septum and relative extent of conal rotation.

A variable degree of conal absorption accompanies failure of conoventricular shift and absence of distal inversion in DORV. In the setting of primary persistence of the subpulmonic conus, the ventricular septal defect tends to be subaortic, and conversely, a persistent subaortic conus is accompanied by a subpulmonic location of the ventricular septal defect.

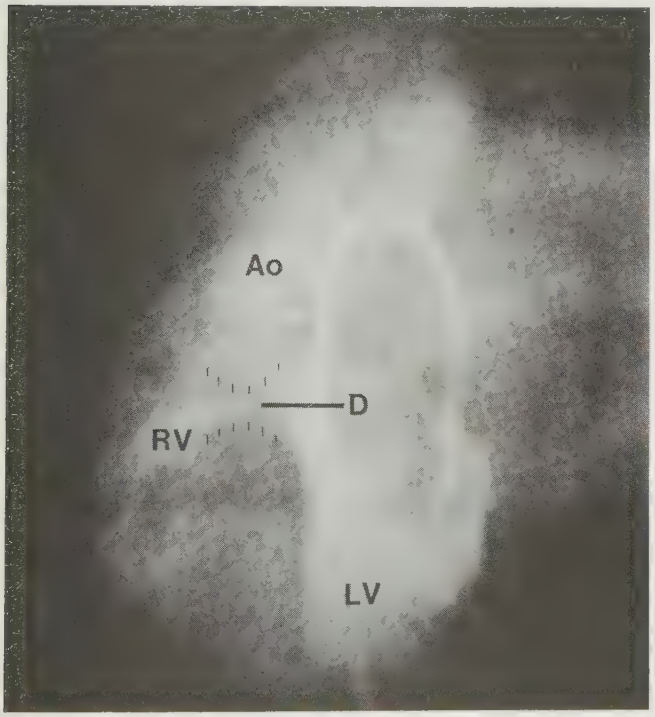

Fig. 72–6. Left ventriculogram in the long axial oblique view in a patient with double-outlet right ventricle and normally related great vessels. A persistent 15 mm Hg systolic gradient between the left ventricle (LV) and right ventricle (RV) present, along with angiographic suggestion of a restrictive subaortic ventricular septal defect (D). At operative repair, superior enlargement of the ventricular septal defect was required to create a nonobstructive tunnel between the left ventricle and aorta (Ao).

PHYSIOLOGY

There are three primary determinants of the circulatory dynamics present in DORV, which result in a spectrum of physiologic profiles that may simulate those of a large ventricular septal defect, tetralogy of Fallot, or transposition of the great arteries. Neufeld proposed a physiologic classification of DORV based on presence or absence of pulmonary stenosis, with subcategorization of the group without pulmonary stenosis based on the relation of the ventricular septal defect to the great arteries and right ventricular outflow tracts.[39,40] Associated left-sided obstructive lesions, the third factor, are also of major importance in DORV, either manifest as coarctation of the aorta or mitral valve anomalies in the newborn, or as progressive subaortic stenosis during childhood.[41]

Pressure Relationships

In most cases of DORV, the ventricular septal defect is nonrestrictive, and the pressures are equal in the right and left ventricles. However, echocardographic study has demonstrated that a nonrestrictive ventricular septal defect should not be assumed to be a large defect, as up to 17% of interventricular communications may require enlargement at operative repair.[42] As the aorta and pulmonary artery both originate from the right ventricle, systolic pressures in the great arteries are equal in the absence of pulmonic or subaortic obstruction.

Pulmonic stenosis is common in DORV, with a reported frequency of 60 to 70% in large series.[30,43] Pulmonic stenosis occurs most frequently in association with a subaortic ventricular septal defect and will result in physiology similar to tetralogy of Fallot. Pulmonic stenosis occurs less frequently in the presence of a subpulmonic ventricular septal defect. Conversely, subaortic obstruction is recognized in approximately 3% of cases of DORV, resulting in a gradient between the right ventricle and aorta.[26] The combination of both pulmonary stenosis and subaortic obstruction

is recognized, and may result in severe ventricular hypertrophy in response to the suprasystemic ventricular pressure.[41]

OXYGENATION

Systemic arterial saturation in DORV will be determined by the magnitude of pulmonary blood flow and the degree of mixing or streaming of oxygenated and deoxygenated blood in the right ventricle. Pulmonary blood flow may be restricted by either pulmonary stenosis or elevated pulmonary vascular resistance, while the relative oxygen saturations in the aorta and pulmonary artery are determined, in part, by the relationship of the ventricular septal defect to the great arteries.

Restricted Pulmonary Perfusion

Severe valvar or subpulmonic obstruction will result in circulatory dynamics similar to tetralogy of Fallot. Systolic pressures in both ventricles and the aorta are equal, with a pressure gradient between the right ventricle and pulmonary artery. As effective pulmonary stenosis occurs most frequently in association with a subaortic ventricular septal defect, there may be preferential streaming of the oxygenated left ventricular blood to the aorta, resulting in an aortic saturation greater than pulmonary saturation. Frequently, however, there is mixing of both right and left ventricular blood with equalization of saturation in both great arteries. In many cases, the catheterization findings are indistinguishable from classic tetralogy of Fallot, with differentiation based on angiography, at which time the diagnosis of DORV with tetralogy is established.

Increased Pulmonary Perfusion

In the absence of significant pulmonary stenosis or elevated pulmonary vascular resistance, the architecture of the right ventricular outflow tract will significantly influence the degree of mixing or streaming of the output of the right and left ventricles. In cases with a subaortic ventricular septal defect, the magnitude of pulmonary flow depends on the ratio of the pulmonary and systemic resistances. Relatively normal pulmonary vascular resistance will be accompanied by marked elevation in pulmonary flow and a pulmonary artery saturation approximating that of the fully saturated aorta. The aortic saturation may exceed pulmonary saturation if left ventricular output is directed to the aorta and little mixing occurs within the right ventricle. The hemodynamic findings then simulate those of a typical ventricular septal defect. The diagnosis of DORV with subaortic ventricular septal defect is established by echocardiography or angiography, as the hemodynamic profile does not allow differentiation from a standard ventricular septal defect. The determination of ventricular septal defect position relative to the aorta based on oxygen saturation alone may be inaccurate, as Sridaromont reported that 40% of patients with subaortic ventricular septal defect and DORV had a pulmonary arterial saturation greater than aortic saturation.[30] The small number of patients with doubly committed and noncommitted ventricular septal defect demonstrated differential aortic and pulmonary saturations, although inadequate in sample size to permit conclusions regarding the position of the ventricular septal defect relative to the great arteries, based on oximetry.

The presence of a subpulmonic ventricular septal defect would appear to correlate with a pulmonary artery saturation exceeding aortic saturation, regardless of the presence or absence of pulmonary stenosis of pulmonary obstructive vascular disease. The oxygenated left ventricular blood recirculates through the ventricular septal defect to the pulmonary artery, establishing the parallel circulation of transposition of the great arteries. A variable degree of mixing may occur in the right ventricle, although cyanosis is present as systemic venous return is directed to the aorta.[44] Clinically, these patients resemble infants with transposition of the great arteries and ventricular septal defect, as both cyanosis and congestive heart failure occur in infancy, and may improve in response to balloon atrial septostomy. Pulmonary flow is determined by pulmonary vascular resistance, and the early onset of pulmonary obstructive vascular disease is recognized.[45] The catheterization diagnosis of DORV with transposition of the great arteries will define both the anatomic and hemodynamic status.

CLINICAL PRESENTATION

The clinical features of DORV are diverse, reflecting the spectrum of physiologic correlates associated with the relationship of the ventricular septal defect to the aorta, the presence or absence of pulmonary stenosis, and associated left-sided obstructive lesions. The presentation and subsequent diagnosis of DORV are usually established in the first months of life, although clinically nonmanifest forms of DORV have been reported.[46] Three clinical groups, reflecting the circulatory dynamics in DORV are recognized: subaortic or subpulmonic ventricular septal defect with pulmonary stenosis, presenting similarly to tetralogy of Fallot; subaortic ventricular septal defect without pulmonary stenosis, presenting as a large ventricular septal defect with pulmonary hypertension; and subpulmonic ventricular septal defect, resembling transposition of the great arteries. These clinical features are modified by the presence of left-sided obstructive lesions.

In 1984 through 1986 my colleagues and I evaluated 19 infants referred for the evaluation of congenital heart disease, in whom the diagnosis of DORV was subsequently established. The clinical features of this group and age at referral are summarized in Fig. 72–7. The diagnosis of DORV in this patient group was established (or confirmed) by echocardiography (n = 18), catheterization (n = 17), corrective surgery (n = 12), or autopsy (n = 4).

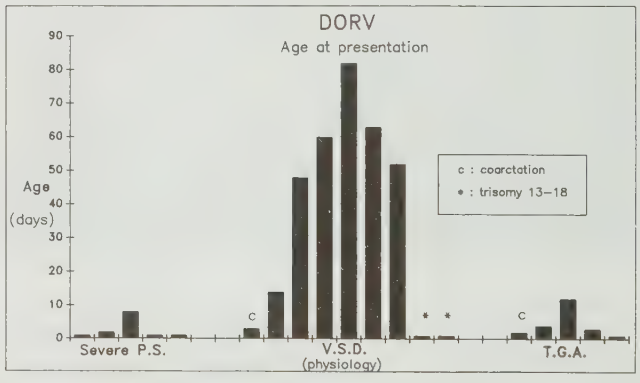

Fig. 72–7. Clinical features and age of referral of infants who underwent evaluation of congenital heart disease, in whom the diagnosis of DORV was subsequently established.

Subaortic or Subpulmonic Ventricular Septal Defect with Pulmonary Stenosis

The clinical features of this group simulate tetralogy of Fallot. Severe cyanosis in the newborn with pulmonary oligemia has recently resulted in uniform early referral of this defect for cardiac evaluation. Cyanosis was determined by the severity of obstruction to pulmonary blood flow, consisting of valvar pulmonic stenosis, subpulmonic stenosis, and obstructive mitral chordae in association with subpulmonic defects. Progressive subpulmonic stenosis was noted in four patients. Beyond the newborn period, cyanosis may be accompanied by hypercyanotic spells, failure to thrive, exertional dyspnea, and polycythemia.

On initial examination, a prominent right ventricular impulse and systolic thrill at the upper left sternal border may be palpable, with an associated harsh systolic murmur and single second heart sound on auscultation. Associated left-sided cardiac lesions are uncommon in this type of DORV.

Subaortic Ventricular Septal Defect without Pulmonary Stenosis

The clinical features in this group were typical of a large ventricular septal defect, with streaming of oxygenated left ventricular blood into the aorta. Minimal, if any, cyanosis was evident, with heart failure and failure to thrive the dominant clinical features. Referral for cardiac evaluation tended to occur later in this group, unless associated left heart lesions were present. Both patients with chromosomal abnormalities (trisomy 13, trisomy 18) and DORV had the ventricular septal defect in the subaortic position, without significant pulmonary stenosis.

A hyperdynamic precordial impulse was noted on initial examination, accompanied at times by a palpable thrill. A grade 3 to 4/6 holosystolic murmur and accentuated pulmonary component of the second heart sound were characteristic, followed by an apical diastolic rumble at the cardiac apex.

The anticipated development of pulmonary obstructive vascular disease in this setting will result in the reduction of pulmonary blood flow, accompanied by loss of the diastolic murmur, and attenuation of the systolic murmur. A very loud and single second heart sound and a diastolic decrescendo murmur of pulmonary insufficiency may evolve.

Subpulmonic Ventricular Septal Defect without Pulmonary Stenosis

The clinical features in this third group are similar to those of transposition of the great arteries with a ventricular septal defect. Variable degrees of cyanosis were manifest in this group, with arterial saturations ranging from 44 to 80%. The presence of coarctation or interruption of the aorta resulted in early clinical congestive heart failure, and referral in the first week of life. The most pronounced cyanosis was evident in the patients with pulmonic stenosis in association with DORV and a subpulmonic ventricular septal defect, accompanied by minimal congestive heart failure.

Initial examination demonstrated cyanosis, and congestive heart failure accompanied by cardiomegaly and diminished or absent femoral pulses, if coarctation was present. In the absence of pulmonary stenosis, tachypnea and pulmonary plethora were evident, accompanied by a loud pulmonary component of the second heart sound and a grade 3/6 systolic murmur and apical diastolic rumble; a systolic ejection click, severe cyanosis, and a systolic thrill and harsh murmur were the clinical hallmarks when severe pulmonary stenosis accompanied a subpulmonic ventricular septal defect.

RADIOGRAPHIC FEATURES

The roentgenographic findings in DORV are determined by the circulatory dynamics, and correlate with the clinical presentation. In general, cardiomegaly and pulmonary vascularity are determined by presence of pulmonary stenosis and the relative pulmonary vascular resistance.

Diminished pulmonary vascularity and a concave left upper heart border are observed when severe pulmonary stenosis accompanies a subaortic ventricular septal defect, as commonly observed in tetralogy of Fallot. In the absence of pulmonary stenosis, cases of DORV with ventricular septal defect demonstrate cardiomegaly, an enlarged main pulmonary artery, and increased pulmonary vascularity. The development of pulmonary obstructive vascular disease will result in reduced pulmonary vascularity, with enlarged proximal pulmonary arteries.

DORV with subpulmonary ventricular septal defect will resemble transposition of the great arteries on the chest roentgenogram, with increased pulmonary vascularity in association with cardiomegaly. In DORV with the aorta anterior and left, the "l-malposition" of the aorta may be recognized by the position of the great arteries, in association with increased pulmonary markings (Fig. 72–8).

The radiographic features of DORV provide corroboration of the clinical findings. Differentiation from other forms of congenital heart disease, however, is based on echocardiography and cardiac catheterization.

ELECTROCARDIOGRAPHIC FEATURES

Although early electrocardiographic studies suggested that the diagnosis of DORV could be suspected prior to cardiac catheterization based on certain aspects of the electrocardiogram,[39,47] this was not substantiated by subsequent studies.[48,49] Electrocardiographic abnormalities are present in most patients with DORV, although none can be considered pathognomonic for this group of defects. Left axis deviation with a counterclockwise frontal plane loop may occur due to displacement of the bundle of His, posterior to the ventricular septal defect.[50] Abnormal early activation of the posterior–inferior left ventricle will result, manifest as left axis deviation and a counterclockwise frontal plane loop. This is an inconstant finding, reported in 6 to 50% of cases of DORV,[47,49] also present in other forms of complex congenital heart disease.

Right ventricular hypertrophy is invariably present beyond the newborn period, reflecting the systemic work of the right ventricle. Left ventricular forces may be normal, or increased in the patient with a subpulmonic ventricular septal defect or restrictive left ventricular outflow tract. Right atrial enlargement may be more frequent in association with pulmonary stenosis, while left atrial enlargement may indicate increased pulmonary blood flow with an intact atrial septum.

First-degree atrioventricular conduction delay is common, particularly when a complete atrioventricular septal defect is present in association with DORV. Abnormalities of atrial rhythm may be

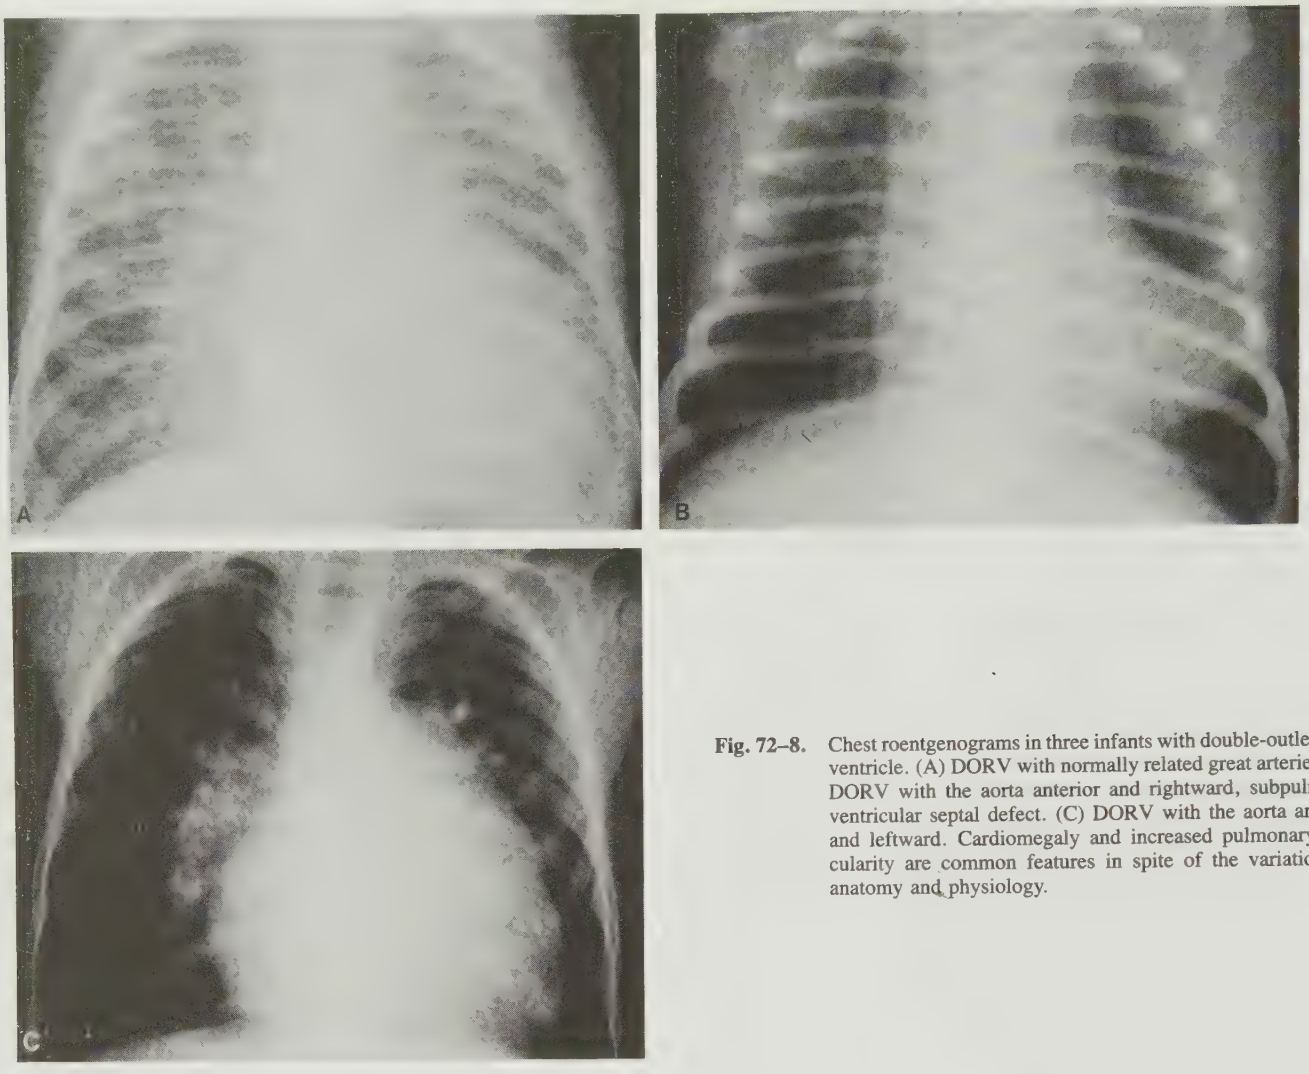

Fig. 72–8. Chest roentgenograms in three infants with double-outlet right ventricle. (A) DORV with normally related great arteries. (B) DORV with the aorta anterior and rightward, subpulmonic ventricular septal defect. (C) DORV with the aorta anterior and leftward. Cardiomegaly and increased pulmonary vascularity are common features in spite of the variations of anatomy and physiology.

present due to atrial enlargement or abnormal sinus node location, if associated abdominal heterotaxia is present.[51]

ECHOCARDIOGRAPHY

The initial echocardiographic studies of DORV were based on M-mode demonstration of mitral-semilunar discontinuity.[52] Subsequent recognition of the subjective nature of this measurement, and a high degree of false-negative and false-positive results, resulted in limited successful application of M-mode echocardiography in the diagnosis of DORV.[53] Further limitations were imposed by the complexities of great artery and atrioventricular valve relations, and inability to define the location of the ventricular septal defect.

Diagnostic criteria to establish the two-dimensional echocardiographic diagnosis of DORV have been proposed, in accordance with the various definitions of DORV.[31,54–55] Because of the extreme heterogeneity of this group of congenital heart defects, standardization remains difficult, with accurate anatomic description required in each case. In general, the following features should be established by echocardiographic examination:

1. The primary commitment of both great arteries to the right ventricle;
2. The spatial relationship of the great arteries;
3. The location of the ventricular septal defect and relation to the semilunar valves; and
4. The presence and type of associated anomalies.

Both parasternal long axis and apical/subcostal imaging will provide documentation of primary origin of both great arteries from the right ventricle,[31,56] while imaging the bifurcation of the pulmonary arteries from the parasternal short axis or subxiphoid views will define the relation of the great arteries.[57] The position of the ventricular septal defect relative to the outflow tracts is best defined from multiple long- and short-axis sweeps (Fig. 72–9).

Increased recognition of the prevalence of associated anomalies in DORV has evolved with two-dimensional echocardiography. In particular, the anatomic variations of atrioventricular valve straddling and override in association with DORV have been elucidated.[58] Also, as previously discussed, anticipation of a potentially restrictive ventricular septal defect following surgical repair has become increasingly frequent.[31]

Two-dimensional echocardiography has advanced the diagnos-

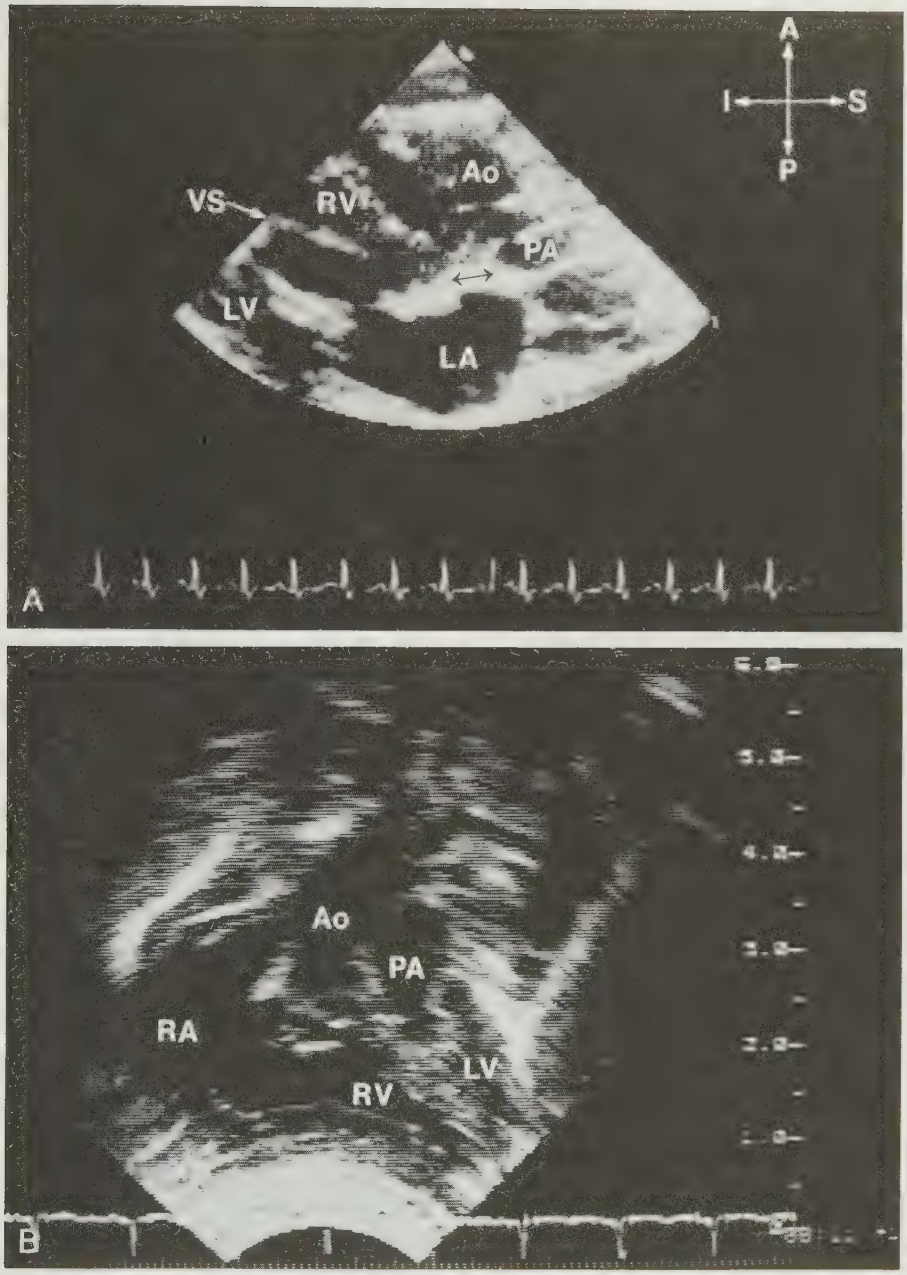

Fig. 72–9. Echocardiographic features of double-outlet right ventricle. (A) Parasternal long axis view, with commitment of both great arteries to the anterior right ventricle (RV), and a parallel course of the posterior pulmonary artery (PA), and anterior aorta (Ao). A large subpulmonic ventricular septal defect is present, with a subpulmonic conus (arrows) separating the mitral valve (MV) from the pulmonary artery. LA = left atrium; RA = right atrium; LV = left ventricle; VS = ventricular septum.

tic recognition of DORV, and differentiation from other conotruncal abnormalities. The prevalence of associated anomalies must be considered during examination, with the perspective that DORV is a definition only of the ventriculoarterial connection.

CARDIAC CATHETERIZATION AND ANGIOGRAPHY

Cardiac catheterization and angiography, in conjunction with two-dimensional echocardiography, provide complete and precise anatomic and hemodynamic delineation in the various forms of DORV. Prior to surgical intervention, the following aspects of anatomy in DORV require definition:

1. Abdominal situs and segmental connections;
2. Atrioventricular-valve morphology and insertion;
3. Relative left ventricular volume;
4. Size and location of the ventricular septal defect;
5. Spatial relationship of the great arteries;
6. The presence of pulmonic or subaortic obstruction; and
7. Aortic arch anatomy.

The hemodynamics of the various forms of DORV have previously been discussed. Although many aspects may be predicted from clinical presentation and echocardiography, important details at catheterization deserve emphasis. In DORV with subaortic ventricular septal defect and severe pulmonic stenosis, left-sided obstructive lesions are rare. However, left ventricular volume may be deficient, due to limited pulmonary venous return, and the primary systolic function of the right ventricle (Fig. 72–3). Although primarily recognized in tetralogy of Fallot, relative hypoplasia of the left ventricle may also occur in DORV.[59,60]

DORV with a subaortic ventricular septal defect without pulmonary stenosis should be approached similarly to a large ventricular septal defect with associated pulmonary hypertension. Evaluation of pulmonary vascular resistance and reactivity are of paramount importance. In addition, relative restriction of the ventricular septal defect or of the subaortic conus occur most frequently in this form of DORV, and must be excluded before surgery.

The patient with a subpulmonic ventricular septal defect and DORV presents the greatest complexities in hemodynamic evaluation. The high incidence of associated left-sided obstructive lesions requires systematic evaluation, along with evaluation of pulmonary vascular resistance due to the potential for early advanced pulmonary obstructive vascular disease. The degree of intracardiac mixing afforded by the ventricular septal defect requires individual case consideration, although the relative ratio of pulmonic to systemic flows appears to determine the effective mixing of the two circuits.[61]

Neufeld et al., in their physiologic categorization of DORV, recognized that the position of the ventricular septal defect was a major determinant in the streaming of oxygenated left ventricular blood.[9] The effective mixing of the two circulations can only be determined by direct measurement of the pulmonary and aortic saturations, as marked streaming may occur in the right ventricle. Increased pulmonary flow with an aortic saturation less than 70%, or a pulmonary saturation 10% greater than aortic, indicate the potential for improvement following balloon or blade atrial septectomy, in the presence of a restrictive atrial septal defect.[62]

The angiographic features of DORV were first reported by Carey and Edwards in 1965.[63] The following diagnostic criteria were proposed: opacification of both great arteries following right ventriculography, a similar horizontal plane of both the aortic and pulmonary valves, frequent anterior malposition of the aorta, and the presence of a "filling defect" dividing the two outflow tracts (Fig. 72–10). These criteria have, in general, proved valid, modified by the subsequent description of the angiographic features of mitral-semilunar discontinuity and the development of biplane angiography.

In DORV, biplane axial angiography must be performed in both ventricles to define the ventricular septal defect and its relation to the great arteries (Fig. 72–11). As stated by Elliot et al., "DORV is a difficult diagnosis to make correctly, but in no other entity is the value of axial angiography more apparent."[64] A left ventriculogram in the long axial oblique projection will define the relation of the anterior mitral valve leaflet to the semilunar valves, and the location, size, and number of ventricular septal defects (Fig. 72–12). Aortography is also requisite to define coronary artery anatomy and to exclude coarctation of the aorta. Coronary artery anomalies are most frequently recognized in patients with DORV and pulmonary stenosis, primarily originating in the left anterior descending artery from the right coronary artery as in classic tetralogy of Fallot,[65] and requires definition before surgical repair involving a ventriculotomy is recommended.

CARDIAC ANOMALIES ASSOCIATED WITH DOUBLE-OUTLET RIGHT VENTRICLE

The physiology and surgical anatomy of DORV are frequently complicated by the presence of additional congenital heart defects. The overall prevalence of associated defects in large series are summarized in Table 72–1. DORV occurs as the only major lesion in less than half of all cases, with frequent associated anomalies of the ventricles, atrioventricular valves, and abdominal situs.[21] However, the association of these defects with the various forms of DORV would not appear to be a random event, as the occurrence of a specific associated defect tends to correlate with the presence of a specific relation between the great arteries and ventricular septal defect.

Obstruction of the Pulmonary Circulation

The various forms of valvar and subvalvar pulmonary stenosis represent the most common anomaly associated with DORV. Variable degrees of pulmonary stenosis occur in 60 to 70% of cases of DORV with a subaortic ventricular septal defect.[26,42] However, in association with a subpulmonic ventricular septal defect and DORV, pulmonary stenosis was not present in certain series,[26] and much less frequent in others. Most recognized cases of persistent common atrioventricular canal with DORV are accompanied by pulmonary stenosis.[66]

Obstructions of the Systemic Circulation

The second common group of cardiac anomalies associated with DORV are generally considered "left heart" obstructive lesions. Obstruction to systemic blood flow in DORV may occur because of a restrictive ventricular septal defect, subaortic or aortic valve stenosis, and coarctation or interruption of the aortic arch. In general, conditions producing obstruction to systemic outflow are more frequently associated with a subpulmonary location of the ventricular septal defect.[67] Also, in contrast to pulmonic stenosis,

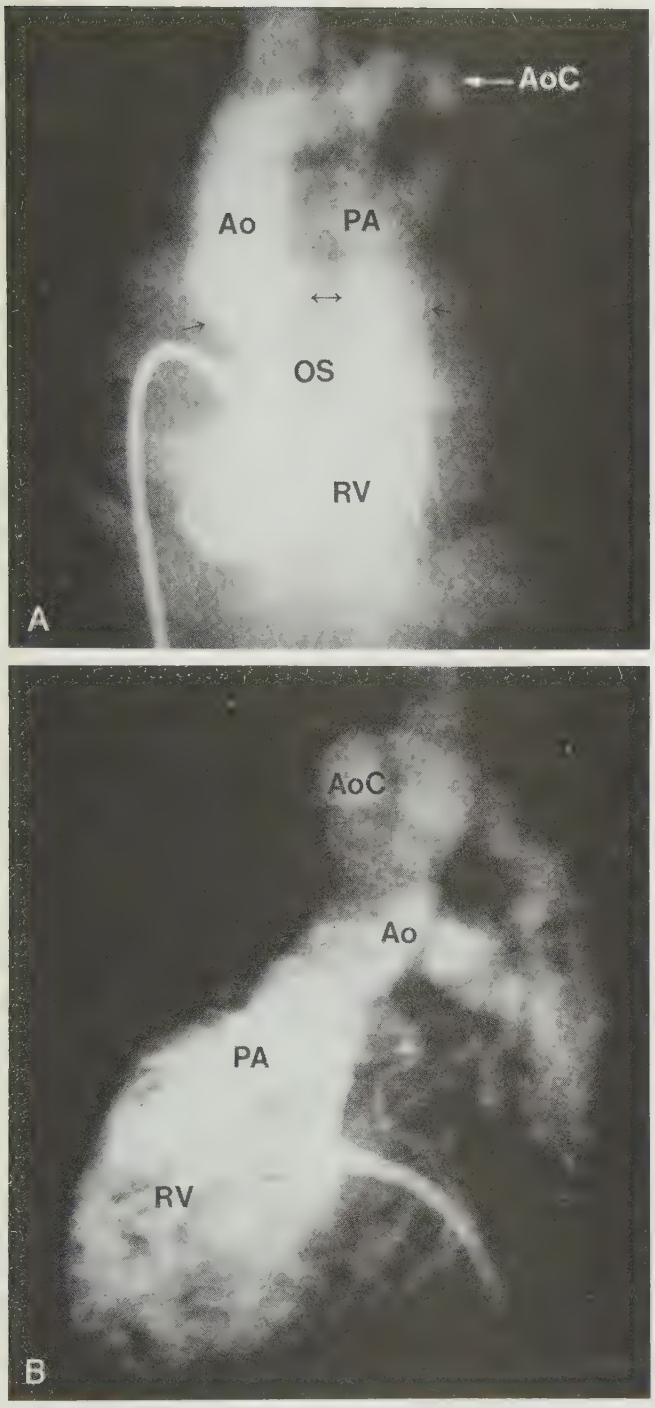

Fig. 72–10. Double-outlet right ventricle with side-by-side great artery relationship and subpulmonic ventricular septal defect. A) The classic angiographic features described by Carey and Edwards are illustrated: 1) filling of both great arteries (Ao and PA) during right ventriculography (RV); 2) a similar horizontal plane of both semilunar valves (arrows); and 3) a filling defect between the great arteries (outlet septum, OS). B) Interruption of the aorta was also present in this case, and an ascending–descending aortic conduit is visualized (AoC) in the lateral view.

this group of defects considerably influences the prognosis of the patient with DORV.

Restriction to left ventricular outflow may be due to a small ventricular septal defect or incorporation of a portion of the atrioventricular valve apparatus into the ventricular septal defect.[28] There is increased recognition of these anatomic variants, which are of major surgical importance, in the current decade, due to the advances of echocardiography.

Muscular hypertrophy of the aortic conus and infundibular septum may result in subaortic stenosis.[68] The potential for progressive subaortic hypertrophy and obstruction may be suggested by angiography before the development of a systolic gradient. Aortic valve stenosis in DORV most frequently is documented in the setting of mitral valve abnormalities.[33]

Coarctation of the aorta represents the most frequent left-sided obstructive lesion in association with DORV.[67] Some authors have noted a definite correlation of coarctation with a subpulmonic ventricular septal defect,[26] although aortic arch abnormalities may occur with any form of DORV (Fig. 72–10).

Left Ventricular Inflow Anomalies

Abnormalities of pulmonary venous return and the mitral valve represent severe but less frequent complexities associated with DORV. No specific correlation between left ventricular inflow restriction and location of a ventricular septal defect is recognized. Restricted or atretic mitral inflow does correlate with hypoplasia of the left ventricle and aortic outflow[66] (Fig. 72–13). As noted, a number of cases of intact ventricular septum in association with DORV have been reported, most in context of mitral stenosis or atresia. Hypoplasia of the left ventricle may also occur when decreased pulmonary blood flow is accompanied by a large atrial septal defect, and a small ventricular septal defect.

Override of either atrioventricular valve annulus or straddling of chordae occurs relatively frequently in DORV. This malalignment of the atrioventricular valves may be of major surgical importance, and requires delineation by two-dimensional echocardiography.[58,68]

Coronary Arterial Patterns

The initial descriptions of coronary artery anatomy in DORV suggested that the origin and course of the two main coronary arteries were essentially identical to those of the normal heart.[69,70] Elliot et al.[69] reported one case of anomalous origin of the right coronary artery from the left main coronary artery, and another case in which two anterior descending coronary arteries were present, with bilateral origin from the right and left coronary arteries.

Sridaromont et al. reported five cases of anomalous origin of the left anterior descending artery from the right coronary artery, all in patients with a subaortic ventricular septal defect and pulmonary stenosis in association with DORV.[30] This coronary anomaly, typically associated with tetralogy of Fallot, emphasizes the anatomic and physiologic continuity of the spectrum of conotruncal abnormalities.

In d-transposition of the aorta and subpulmonary ventricular septal defect, coronary artery anatomy is similar to that observed in transposition of the great arteries.[71] The right coronary artery originates from the posterior sinus of Valsalva, with origin of the left main coronary artery from the left sinus. Wilcox et al.[3] noted a frequent coronary anomaly in DORV, regardless of the origin

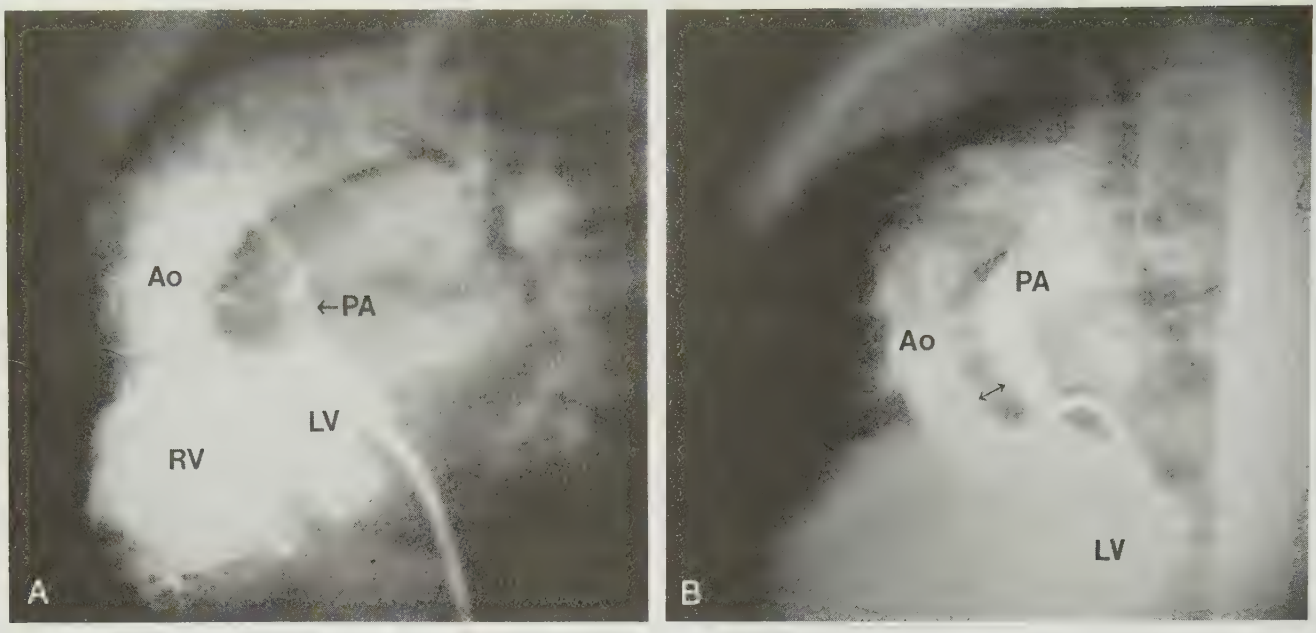

Fig. 72–11. Lateral-projection right ventriculogram (A) and left-anterior-oblique left ventriculogram (B) demonstrating persistence of a bilateral conus (arrows), with a poorly expanded subpulmonic conus. However, the posterior pulmonary artery (PA) is committed to the left ventricle (LV), and thus this case would not be classified as double-outlet right ventricle. The absence of arterial override was confirmed at surgical repair. The importance of axial biplane angiography, and the occurrence of a bilateral conus in other forms of congenital heart disease are emphasized. Ao = aorta; RV = right ventricle.

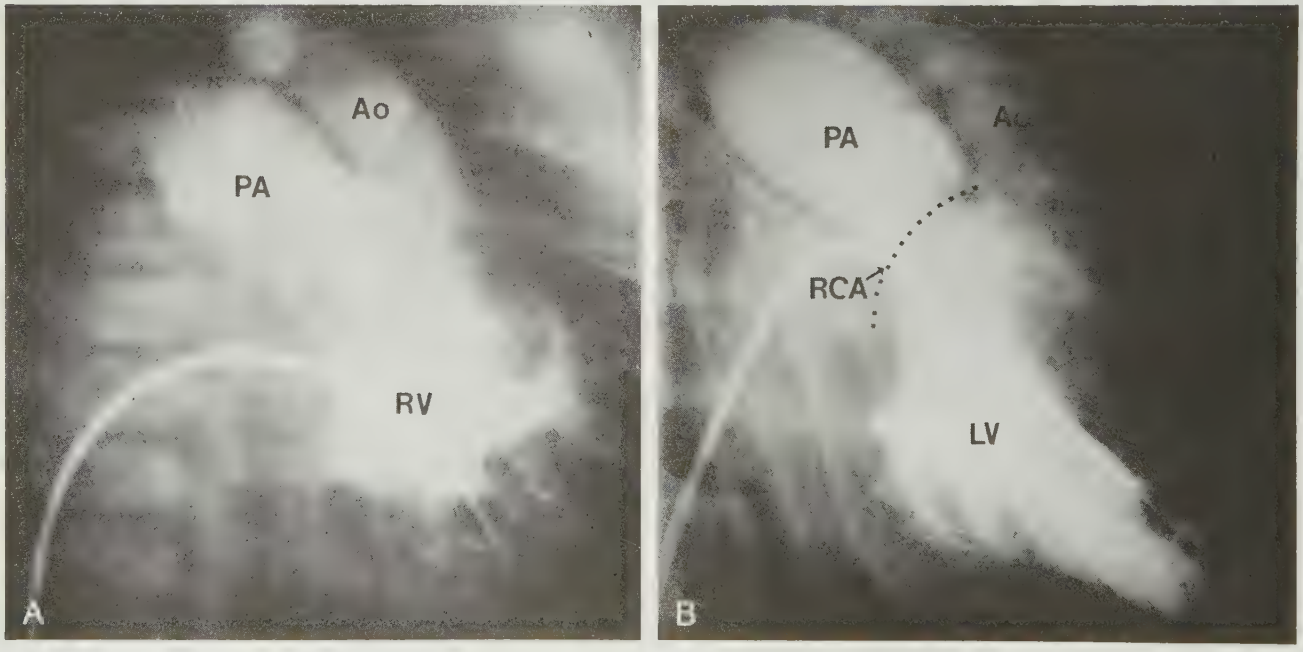

Fig. 72–12. Double-outlet right ventricle with levomalposition of the great arteries and subpulmonic ventricular septal defect. A subaortic ventricular septal defect provides the only communication with the left ventricle. Long-term palliation has been attained in this patient following a modified Norwood procedure.

of the right coronary artery (i.e., from the anterior or posterior sinus): an anterior origin of the left anterior descending artery, with a subsequent course inferior to the pulmonary annulus in the ventricular free wall, which could preclude right ventriculotomy.

In l-malposition of the aorta with DORV, the right coronary artery courses immediately beneath the pulmonary annulus. The subpulmonary conus tends to be poorly expanded in this anatomy, resulting in infundibular and annular stenosis.[72] The surgical approaches to pulmonary outflow reconstruction must be based on anticipation of this anatomy.

A number of patterns of coronary arterial anatomy have been recognized in patients who have had successful arterial transfer in their repair of DORV.[73] However, given the frequency and variability of this anatomy, preoperative angiographic definition of the coronary arteries would appear warranted, regardless of the type of repair used (Fig. 72–14).

CONDUCTION SYSTEM

The course of the atrioventricular node and His-Purkinje system in DORV with atrioventricular concordance is similar to that described for isolated perimembranous ventricular septal defects.[74] The atrioventricular node begins between the coronary sinus and medial leaflet of the tricuspid valve, with the penetrating portion of the His bundle passing through the central fibrous body and subsequently beneath the crest of the ventricular septal defect. This relatively normal course is anticipated, as the development of the atrioventricular node and bundle branches are related primarily to the endocardial cushions and posterior ventricular septum, not the bulbus cordis.[75] In subaortic, subpulmonary, or doubly committed defects with a caudal muscular border, the conduction tissues are further displaced away from the superior margin of the defect. Thus, if surgical repair requires enlargement of the ventricular septal defect, this may be done at the apical aspect of the interventricular communication, and include the outlet septum.[76] The exception to this rule occurs when a muscular inlet defect occurs in association with DORV, when a superior course of the conduction tissues is recognized.[77]

COMPLEX ANATOMY ASSOCIATED WITH DOUBLE-OUTLET RIGHT VENTRICLE

Dextrocardia, Atrioventricular Discordance, and Double-Outlet Right Ventricle

Situs solitus of the atria and abdominal viscera, accompanied by atrioventricular discordance and dextrocardia are recognized to occur in conjunction with DORV.[77] The discordant ventricular loop

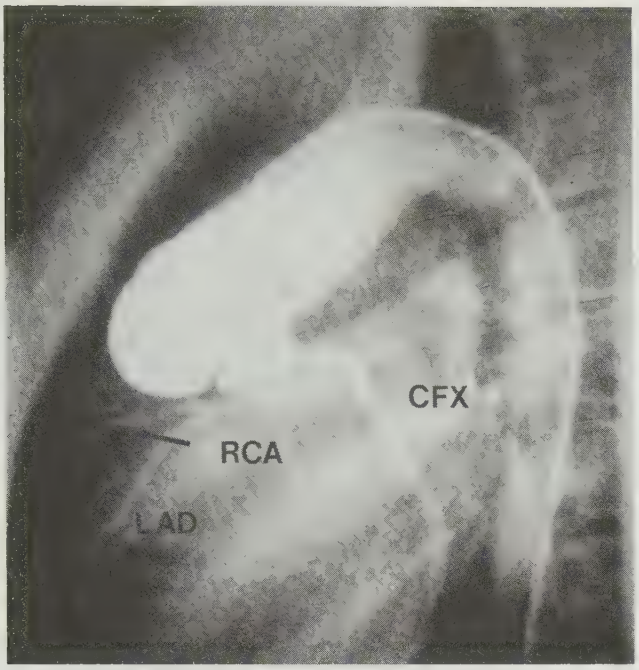

Fig. 72–14. Aortogram in the lateral view, demonstrating a single coronary artery arising from the left sinus of Valsalva in association with double-outlet right ventricle and a superior–anterior ventricular relationship (see Fig. 72–15). A dominant circumflex (CFX) artery courses posteriorly in the usual course, in addition to anterior distribution of the right coronary artery (RCA) and left anterior descending (LAD) artery.

(''l-loop'') is accompanied by levomalposition of the great arteries, with a persistent bilateral conus and origin of both great arteries from the morphologic right ventricle. Classification of this anatomy as ''situs solitus/l-loop/d-DORV'' has been suggested to emphasize the right and anterior position of the aorta.[78] The ventricular septal defect is in a subpulmonic position, usually accompanied by both valvar and subvalvar pulmonic stenosis.

Angiography will define the morphologic right and left ventricles and the relation of the great arteries (Fig. 72–15). Surgical correction of this constellation of defects was first reported by Kiser et al., by closure of the ventricular septal defect, transection of the pulmonary artery, and use of an extracardiac conduit to establish continuity between the morphologic left ventricle and pulmonary artery.[79]

Superior–Inferior Ventricles with Double-Outlet Right Ventricle

A superior–inferior relationship of the ventricles, with origin of both great arteries from the superior right ventricle, represents an additional complexity in the spectrum of DORV.[80] A variety of segmental connections and arterial relationships have been described in this complex, thus categorization of this complex is not appropriate. Inherent to this form of DORV is a ventricular septal defect located in the inlet septum, frequently associated with straddling of the atrioventricular valve chordae, which may preclude corrective surgical repair[19] (Fig. 72–16).

Single Atrioventricular Valve Connection with Double-Outlet Right Ventricle

Double-outlet right ventricle has been reported in association with the various atrioventricular valve abnormalities, reflecting the embryonic nature of this defect. A common atrioventricular canal defect in association with DORV and pulmonary stenosis is the most common of these rare constellations of congenital heart defects, which may be accompanied by total anomalous pulmonary venous return and asplenia.[66,81] DORV has also been reported in association with tricuspid atresia, double-chambered right ventricle and the trisomy 18 syndrome.[82–85]

NATURAL HISTORY

The anticipated clinical course of the patient with DORV who does not undergo surgery is determined by the associated physiology, and the presence and severity of associated congenital heart defects. DORV with a large subaortic ventricular septal defect will result in the development of pulmonary obstructive vascular disease, at least as rapidly as in the patient with a large, isolated ventricular septal defect.[86] Sondheimer reported four deaths and two additional cases of advanced pulmonary obstructive vascular disease in 18 patients with DORV and subaortic ventricular septal defect evaluated between 1956 and 1975.[26] In the same series, the natural history of DORV with subaortic ventricular septal defect and pulmonary stenosis was the most favorable, with long-term survival and patient-management protocols similar to those used in tetralogy of Fallot. Long-term survival, either by palliative systemic-pulmonary shunting or corrective surgery, remains the anticipated course in this group.

As DORV with subpulmonary ventricular septal defect is infrequently accompanied by pulmonic stenosis, the early development of pulmonary obstructive vascular disease, as in patients with transposition of the great arteries and ventricular septal defect, is anticipated. This may be compounded by the presence of left-sided obstructive lesions, in particular, coarctation of the aorta, which remains associated with a high rate of early mortality.[43,87]

CORRECTIVE SURGERY FOR DOUBLE-OUTLET RIGHT VENTRICLE

Analysis of the results of surgical correction of DORV is complicated, due to the multiple morphologic subsets of this defect, associated congenital heart defects, and differing surgical protocols. The successful intracardiac repair of DORV was first performed by Kirklin in 1957, creating an interventricular tunnel to connect the left ventricle to the aorta via the ventricular septal defect.[88] The establishment of left ventricle–aortic continuity in the patient with a subaortic ventricular septal defect has remained the classic form of repair of DORV since its inception 30 years ago. However, the surgical approach to DORV with subpulmonic ventricular septal defect has remained controversial since the first successful repair in 1967.[89]

As proposed by Lev, and recently analyzed by Kirklin, the commitment of the ventricular septal defect to the great arteries and location of the ventricular septal defect in the interventricular septum are the crucial variables in the repair of DORV.[2,11,90] The surgical results for DORV with a subaortic or doubly committed

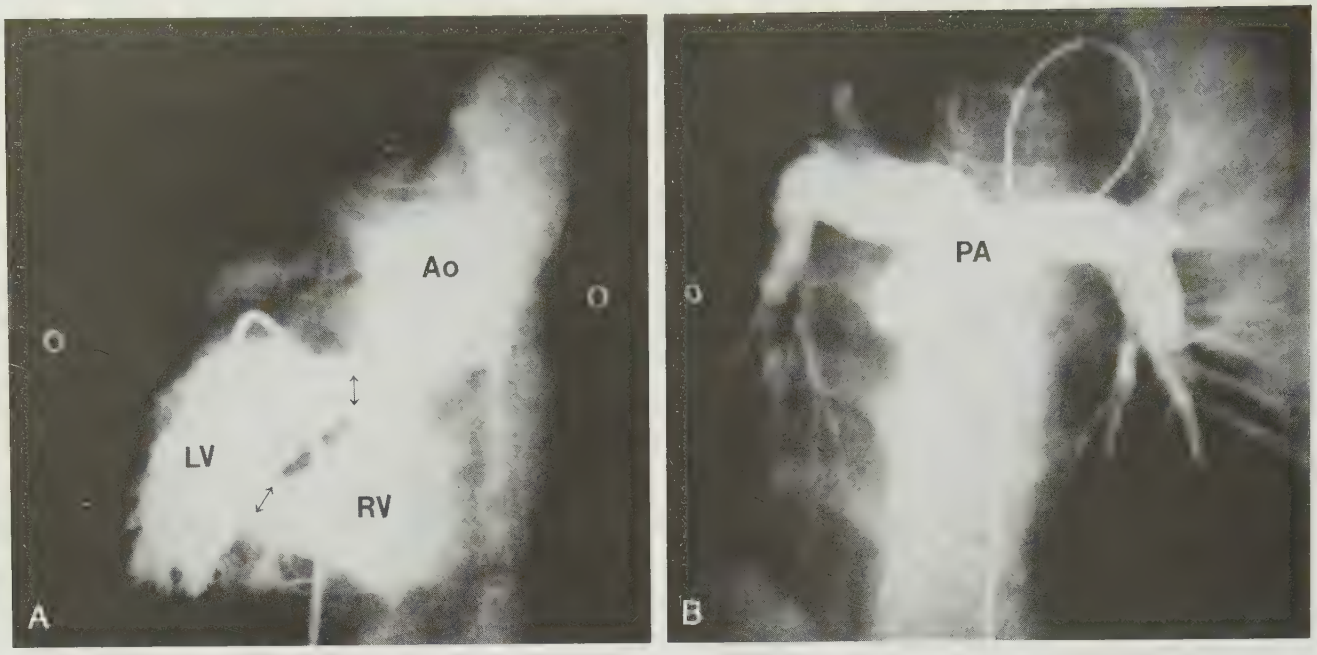

Fig. 72–15. Double-outlet right ventricle with dextrocardia, atrioventricular discordance, and associated pulmonary valve atresia. (A) Frontal-view left ventriculogram (LV) demonstrating two ventricular septal defects (arrows), and an anterior and left origin of the aorta (Ao) from the right ventricle (RV). (B) Pulmonary arteriogram (same projection) illustrating alignment of the pulmonary annulus (PA) above the morphologic right ventricle. This case is classified as DORV, as both great arteries are aligned above the right ventricle, although only the aorta is connected to the right ventricle at the subaortic conus.

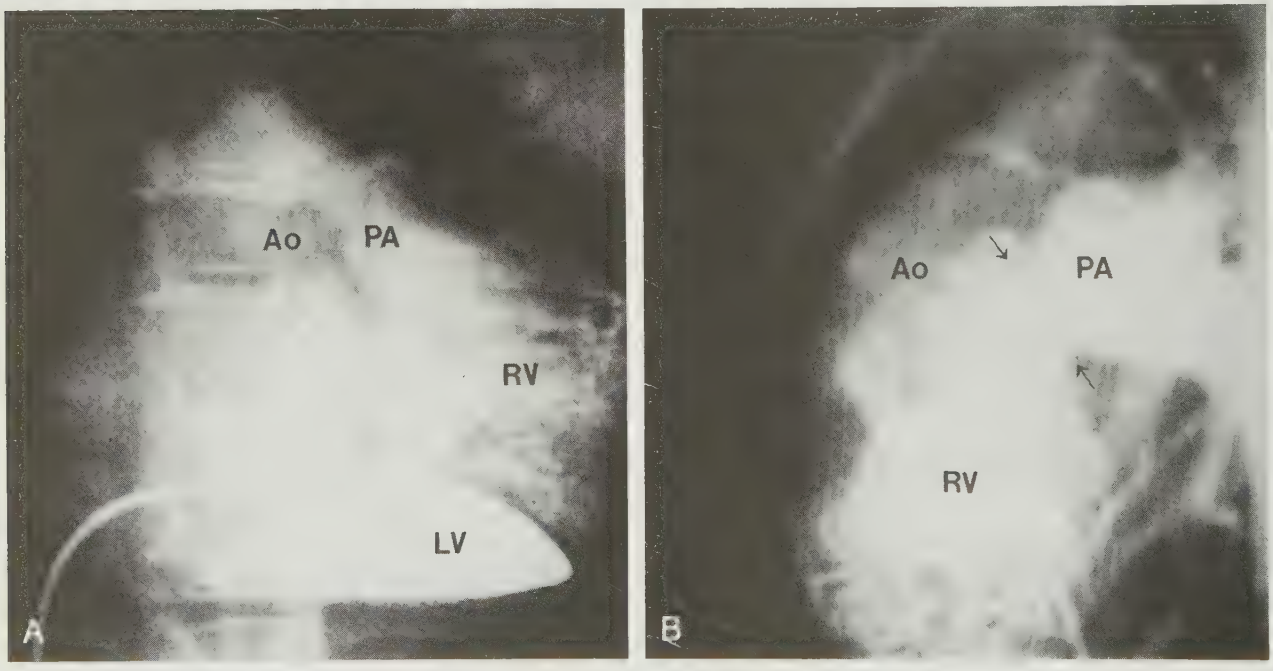

Fig. 72–16. Double-outlet right ventricle with an inferior and hypoplastic morphologic left ventricle, and a superior right ventricle. (A) Frontal-view left ventriculogram (LV), demonstrating multiple ventricular septal defects, which provide the only outlet for this chamber. Ao = aorta; PA = pulmonary artery; RV = right ventricle. (B) Lateral view of the superior right ventricle (RV), demonstrating coarse trabeculation, with an anterior origin of the aorta (Ao) and a posterior pulmonary artery (PA), which had previously been banded (arrows).

ventricular septal defect have progressively improved; currently, a low operative mortality and excellent long-term results are anticipated. However, the multiple surgical approaches to DORV with a subpulmonic or noncommitted ventricular septal defect emphasize the complexity of this repair, with less favorable results.

Double-Outlet Right Ventricle with Subaortic Ventricular Septal Defect

In the absence of significant associated congenital heart disease, the proximity of the ventricular septal defect to the aorta is of major importance in the establishment of continuity between the ventricular septal defect and the subaortic outflow tract.[2] Our current protocol, that reported by Kirklin et al., would favor primary intracardiac repair of DORV with subaortic ventricular septal defect before 12 months of age, in the absence of significant associated congenital heart disease.[11] Pulmonary artery banding, as a preliminary procedure, is not indicated in uncomplicated forms of DORV.

Although an initial operative mortality of 22% was reported in DORV with subaortic ventricular septal defect,[91] current experience would predict long-term survival to exceed 95%, with an excellent functional result.[92] The enlargement of a restrictive ventricular septal defect does not appear to be an incremental surgical risk factor; however, this must be recognized preoperatively.[93] Within this morphologic subset, the presence of severe mitral or left ventricular hypoplasia is considered an uncorrectable cofactor.

The similar repair of the doubly commited ventricular septal defect, with creation of a left ventricular–subaortic tunnel, does not present a significant increase in operative risk; however, an increased incidence of the late development of discrete subaortic stenosis following repair has been reported.[94]

Double-Outlet Right Ventricle with Pulmonic Stenosis

The initial surgical series of DORV with pulmonary stenosis in association with a subaortic ventricular septal defect reported an overall mortality of 32% in 22 patients.[95] Exclusion of the first four patients in this series, however, resulted in an operative mortality of 16%. In a subsequent study, operative mortality was reduced to 11%, although late death from arrhythmia was frequent.[96] In the current decade, patients with DORV, subaortic ventricular septal defect, and pulmonary stenosis are managed in accordance with institutional protocols applied to tetralogy of Fallot.[97] When simple repair of the pulmonary obstruction appears feasible by angiography, intracardiac repair at 6 to 12 months of age is recommended. The risks of this repair do not appear different from those for repair of DORV with subaortic ventricular septal defect in the absence of pulmonic stenosis.[11] However, as this form of DORV is frequently accompanied by profound newborn cyanosis, severe dysplasia of the pulmonary arteries, or anomalies of the coronary arteries, initial palliative shunting is often required.[96,98] When complex repair to include a right-ventricle-to-pulmonary-artery homograft conduit is anticipated, preliminary palliative shunting is also indicated, with definitive repair delayed until four or five years of age.[99]

Double-Outlet Right Ventricle with Subpulmonary Ventricular Septal Defect

In general, surgical survival rates are lower in patients with DORV and a subpulmonary or noncommitted ventricular septal defect.[11] Historically, three surgical approaches to the Taussig–Bing type of DORV have been performed: 1) closure of the ventricular septal defect to tunnel the left ventricle output to the pulmonary artery, with subsequent atrial baffle procedure (Mustard or Senning); 2) a long interventricular tunnel to establish left-ventricle-to-aorta continuity, with direct or conduit continuity of the right ventricle to the pulmonary artery; and 3) left-ventricle-to-subpulmonary-outflow-tract tunnel, with an arterial translocation procedure (Jatene or Damus–Stansel–Kaye).

In most cases of DORV with subpulmonary ventricular septal defect, the defect is bordered superiorly by the pulmonary valve, and the ventricular septal defect can be repaired in a manner such that an unobstructed left ventricle–pulmonary artery connection is formed. In conjunction with an atrial baffle procedure, this type of repair of the Taussig–Bing heart was first reported in 1969.[100] However, the venous switch (Mustard or Senning) and ventricular septal defect closure in DORV have remained associated with a high operative and late mortality rate in most centers.[90,101] Because of these poor results, direct ventricular septal defect closure accompanied by arterial translocation for repair of the Taussig–Bing type of anatomy has become the preferred approach.[11,102–104] The principles of coronary transfer do not appear different from those applied in classic transposition.[101] Alternatively, recognition that the infundibular septum and ventriculoinfundibular fold are devoid of conduction tissue has allowed enlargement of the ventricular septal defect, with subsequent placement of a tunnel to establish left-ventricle-to-aorta continuity in a limited number of these patients.[105,106]

Regardless of the type of repair preferred, surgery should be attempted by three months of age, due to the rapid evolution of pulmonary vascular disease and myocardial hypertrophy. Increased patient numbers and longterm followup will be required to determine the procedure of choice in this type of anatomy. However, current data suggest superior results with the interventricular tunnel or arterial transfer as compared with a venous switch and ventricular septal defect closure (Fig. 72–17).

PATIENT STATUS FOLLOWING SURGICAL REPAIR OF DOUBLE-OUTLET RIGHT VENTRICLE

The heterogeneity of malformations that constitute DORV make analysis of the outcome of corrective surgery difficult. However, in the current decade, improved hemodynamic results have been reported in most forms of DORV, associated with a low operative mortality rate.[11,92,107]

Perioperative mortality following repair of DORV has been attributed to persistent low cardiac output, residual pulmonary hypertension, and hemorrhage. Recent clinical and hemodynamic followup suggests that most patients surviving repair of DORV in the current era are New York Heart Association Functional Class 1. Early primary repair of DORV, as opposed to initial palliation with subsequent repair, is no longer projected as a risk factor and may further improve surgical results.

Residual hemodynamic abnormalities, the potential need for reoperation, and late postoperative arrhythmias are primary considerations in the followup of these patients. A residual ventricular septal defect ($Qp/Qs > 1.5$) may occur in a significant number of patients, particularly following construction of a complex interventricular tunnel. Subpulmonic stenosis has been recognized, due

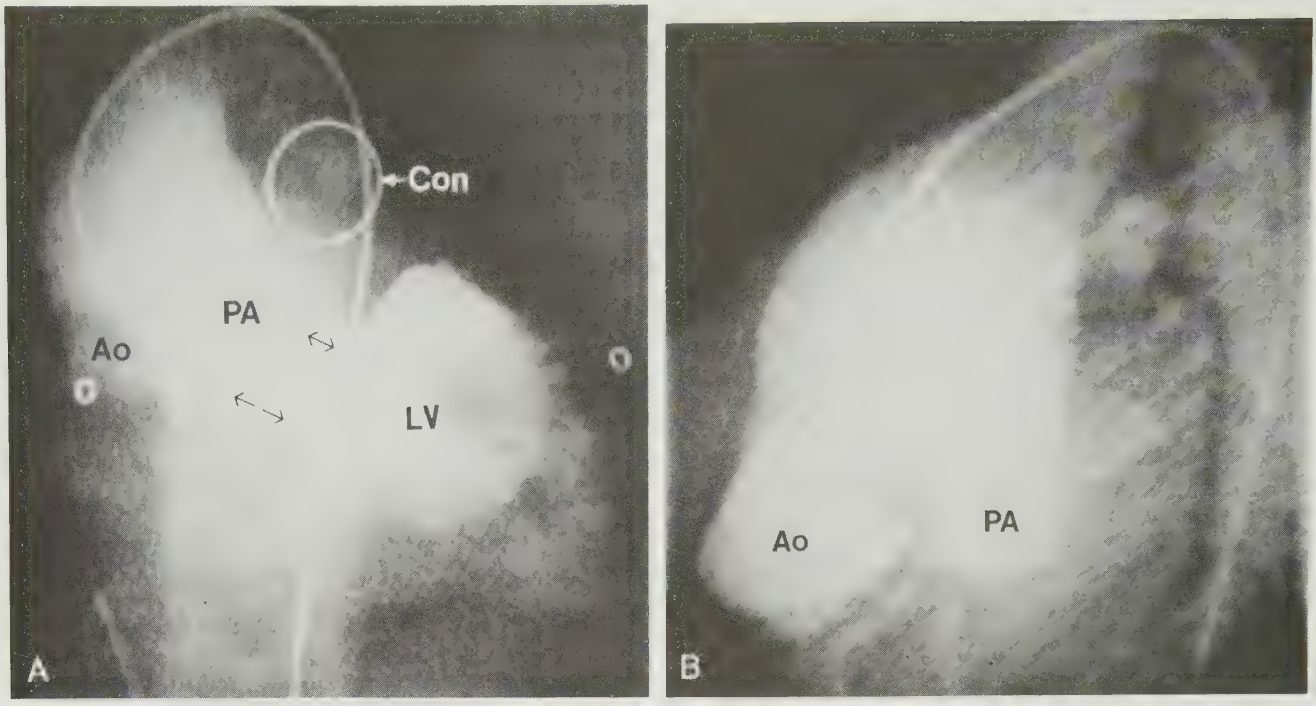

Fig. 72–17. Double-outlet right ventricle with subpulmonic ventricular septal defect, following correction with Kaye–Damus–Stansel procedure. A) Left ventriculogram (LV) demonstrating the subpulmonic conus (arrows), and filling of the proximal main pulmonary artery (PA) followed by opacification of the ascending aorta (Ao). The valved conduit (Con) establishing right ventricle–pulmonary artery continuity is evident. B) Lateral-view aortogram, emphasizing the anterior–posterior great artery relationship, and wide area of arterial anastomosis establishing the arterial repair, without associated coronary translocation.

either to muscular hypertrophy of the conus or tunnel compromise of the subpulmonic outflow tract, although not severe in degree. Less frequently, subaortic stenosis due to the baffle obstruction may produce a significant systolic ejection gradient requiring revision. As in other complex forms of congenital heart disease, ventricular dysfunction may evolve in association with longterm palliation.

Indications for reoperation are a function of multiple variables, both anatomic and hemodynamic. The reoperations for DORV have included replacement of an extracardiac conduit, repair of tunnel dehiscence or tunnel revision, closure of residual ventricular septal defects, and atrioventricular valve replacement.[11,107]

A disturbing prevalence of cardiac arrhythmias and sudden cardiac death following repair of DORV has been recognized, with late sudden death potentially exceeding the operative mortality.[96,108] Definitive repair at an older age and persistent elevation of pulmonary artery pressure have been identified as significant factors for this risk. However, other series have reported no significant postoperative dysrhythmias or sudden death following repair of DORV.[92,107] From our perspective, persistent atrial arrhythmias, ventricular ectopy, or syncope provide justification for postoperative electrophysiologic studies in this patient group. Given the anatomic and hemodynamic similarities to the repair of tetralogy of Fallot, or an arterial or venous switch procedure associated with ventricular septal defect closure, the indications for electrophysiologic study should not differ.[109]

DOUBLE-OUTLET LEFT VENTRICLE

Perhaps the rarest of ventriculoarterial connections, and at times the most controversial, double-outlet left ventricle (DOLV) has been reported in over 100 cases to date.[5] The unequivocal description of a case of DOLV with an intact ventricular septum in 1970 confirmed the existence of this anomaly,[110] which previously had been considered an embryologic improbability or impossibility.[111,112] Subsequent definition of "double-outlet ventricle" as the origin of one and 50% or more of the other great artery from the same ventricle has resulted in increased recognition of this anomaly.[4] As Bharati et al., have indicated, as more cases of DOLV are recognized, similar variations in great artery relationship and ventricular septal defect position will be described, analogous to DORV.[113]

In most cases of DOLV there is a hypoplastic or deficient infundibular septum, and poorly expanded subpulmonary conus. The successful surgical correction of this type of DOLV, which is similar to tetralogy of Fallot, was first reported in 1971.[114] Subsequently, multiple anatomic variations in association with DOLV have been described.

The diagnosis of DOLV should be considered cautiously when the presence of ventricular inversion (l-loop) in association with DORV has not been excluded. As of this writing, and in a recent review, no cases of DOLV have been documented by echocardiography.[115] Although extremely rare, DOLV may be associated with abnormalities of any aspect of cardiac anatomy, and a segmental approach to diagnosis is mandatory. Palliative or corrective surgery is usually feasible, following accurate anatomic definition.

CHAPTER 73

Ventricular Inversion

Charles E Mullins

DEFINITION

Ventricular inversion in combination with transposition of the great arteries is referred to as L-transposition,[1] "corrected transposition,"[2] "physiologically or congenitally[3] corrected transposition," or "atrioventricular discordance with transposition."[4] Ventricular inversion alone is defined simply as atrioventricular discordance.[4] Specifically, the *morphologic* right atrium is connected to the *morphologic* left ventricle, and/or the *morphologic* left atrium is connected to the *morphologic* right ventricle (Fig. 73–1). In this chapter, all subsequent references to *right* and *left* in relation to chambers will refer only to the *anatomic structure* or *morphology* of the chamber without regard to the spatial relationships, the connections to other chambers or vessels, or the physiologic function of the chamber. This use of the adjectives is analogous to the use, for example, with the right or left hand. The hands were named according to the side of the body to which they were attached, however, regardless of where the hand is or what task it is performing (e.g., over the head, behind the back or even totally disconnected from the body), the hand morphologically remains a right or left hand and one does not refer to the "morphologic" or "anatomic" right or left hand. As long as one uses only morphology to define the chambers, this analogy holds true for the cardiac chambers and no redundant adjectives such as anatomic, structural, or morphologic right or left will be used in this chapter.

Each of the four cardiac chambers has distinct identifying features independent of their spatial location or cardiac connections. The right ventricle is identified by its coarse apical trabeculations and by the muscular conus separating the inflow or sinus portion from the infundibular portion of the ventricle.[5] The tricuspid valve, a right ventricular structure, has characteristic multiple papillary muscle attachments to the ventricular septum and is separated from the semilunar outflow valve by the conus. The left ventricle has much finer apical and septal trabeculations, and has no outflow conus or infundibulum.[5] The atrioventricular mitral valve, which is structurally part of the left ventricle, has a direct fibrous attachment to the outflow semilunar valve of the left ventricle. The anterior leaflet of the mitral valve actually forms one side of the outflow tract of the left ventricle. The mitral valve usually has two distinct papillary muscles and no septal attachments.

The right atrium is best identified angiographically and anatomically by the very broad base and blunt configuration of the right atrial appendage as well as the extension of the pectinate muscles from the appendage into the right atrium.[5] This is in contrast to the left atrium with its usually narrow-based, longer, and finger-like left atrial appendage with no pectinate muscular extension into the left atrium.[5] When the systemic veins follow their usual course, they usually enter the right atrium and help to identify the right atrium although this is not a reliable determinant because of known anomalous systemic venous connections. The same holds true for the left atrium and the pulmonary veins.

Ventricular inversion can be an isolated anatomic defect and, as such, is not necessarily associated with any other structural defect. However, ventricular inversion usually is found in association with other cardiac defects as the major embryologic and structural abnormality in a variety of complex lesions. Ventricular inversion is usually, but not necessarily, associated with transposition of the great arteries. In this common association with

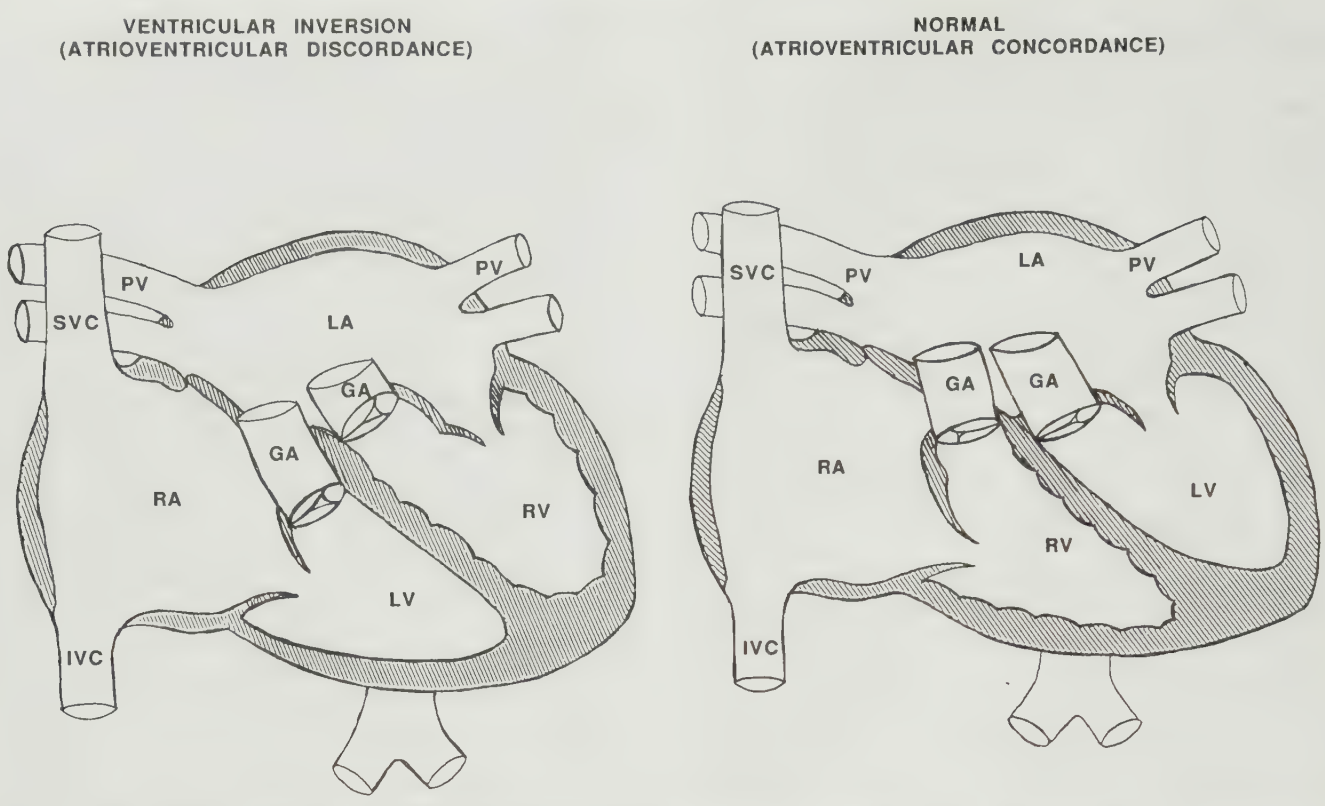

Fig. 73–1. Line diagrams of ventricular inversion–atrioventricular discordance (left diagram) compared to a diagram of normal atrioventricular connection–atrioventricular concordance (right diagram). In ventricular inversion, the right atrium connects to the smooth-walled left ventricle. There is direct fibrous continuity between the right atrioventricular valve and the right semilunar valve (absence of a conus). In ventricular inversion, the left atrium connects to the trabeculated (scalloped inner wall) right ventricle. The right ventricle has a muscular mass (conus) separating the left atrioventricular valve and the left semilunar valve. This compares to the normal (right diagram) where the right atrium connects to the right ventricle and the left atrium connects to the left ventricle.

transposition of the great arteries, the terminology L-transposition or corrected transposition refers respectively to the commonly occurring spatial relationships of the two great arteries with this combination, or to the physiologically corrected status of the combined lesions. Because of the much higher incidence of ventricular inversion in association with transposition, the majority of this chapter will be on the discussion of ventricular inversion with transposition of the great arteries.

INCIDENCE

Ventricular inversion with two well-defined ventricles, even with the commonly associated transposition of the great arteries and other associated lesions such as ventricular septal defect and pulmonary stenosis, is a relatively rare lesion accounting for only about 0.5% of clinically apparent congenital heart disease.[6,7] Of this total group of patients with ventricular inversion and transposition of the great arteries, probably fewer than 1% have no other associated abnormalities.[8–10] Isolated ventricular inversion with normally connected great arteries (i.e., without transposition) occurs in fewer than 1% of all cases of ventricular inversion. In addition to those cases of ventricular inversion with two well-defined ventricles, as many as 75% of all cases of univentricular hearts (as described in Chapter 74) embryologically are varieties of ventricular inversion. Because of their unique anatomy and different hemodynamic problems, univentricular hearts usually are not included under the discussions or tabulations of ventricular inversion.

EMBRYOLOGY: L-LOOPING

The normal heart with normal atrioventricular relationships is a result of so-called Dextro or D-looping of the embryonic heart tube.[11] The development of ventricular inversion or atrioventricular discordance and the resultant anatomy is explained by the embryologic phenomena or Levo or L-looping of the embryonic heart tube[12] as opposed to this normal D-looping. Knowledge of this embryology helps in the understanding of ventricular inversion and the associated lesions.

The embryonic heart is formed from primitive blood islands into a relatively straight and undifferentiated tube at approximately 20 days' gestation.[11,13] Within the same day of gestation, the segments of the tube differentiate into the primitive aortic arches, the bulbus cordis, the primitive ventricle, the sinus venosus, and the venous channels. The bulbus cordis will develop into the truncus and the right ventricle whereas the primitive ventricle becomes the early left ventricle. The primitive ventricle separates from the venous confluence by primordial atrioventricular valve tissue. Shortly after the differentiation within the cardiac tube, at about 23 days' gestation, the blood flow in the venous channels begins

to lateralize, normally with the systemic veins lateralizing to the right side of the embryo into the primitive right atrium. At almost the same time, the center of the tube begins to fold on itself and rotate anteriorly, normally to the right of the embryo, D-looping (Fig. 73–2). This brings the primitive right ventricle in a front-to-back apposition to the rightward lateralized systemic veins and side by side to the primitive left ventricle. Simultaneously, the left-sided venous chamber is producing an outpouching dorsally and on the left that will contact and connect with the pulmonary venous buds arising from the lungs. Also, the atrioventricular valve is migrating to the right within the embryonic heart to straddle the inflow of both the right and left ventricles. This produces situs solitus of the atria with the normal D-looping; the right or systemic venous atrium is in apposition to and drains into the right ventricle. The eventual left or pulmonary venous atrium with the attached pulmonary veins remains connected to the left ventricle (Fig. 73–3) (i.e., atrioventricular concordance with situs solitus of the atria).

With isolated L-looping of the heart tube, the heart tube folds to the left while all of the other lateralization remains the same (situs solitus of the atria)[12] (Fig. 73–4). The right ventricle comes in apposition to the left or pulmonary venous atrium, and the left ventricle remains in apposition to, and connected to, the right or systemic venous atrium (Fig. 73–5) with resultant atrioventricular discordance or ventricular inversion with situs solitus of the atria.

If the early cardiac venous structures had lateralized to the left so that the systemic veins were on the left of the embryo, the L-loop would have resulted in the proper or concordant atrioventricular relationships (nonventricular inversion) but with situs inversus of the atria. Similarly, with the left-sided lateralization (situs inversus) of atria, the D-looping of the heart tube would

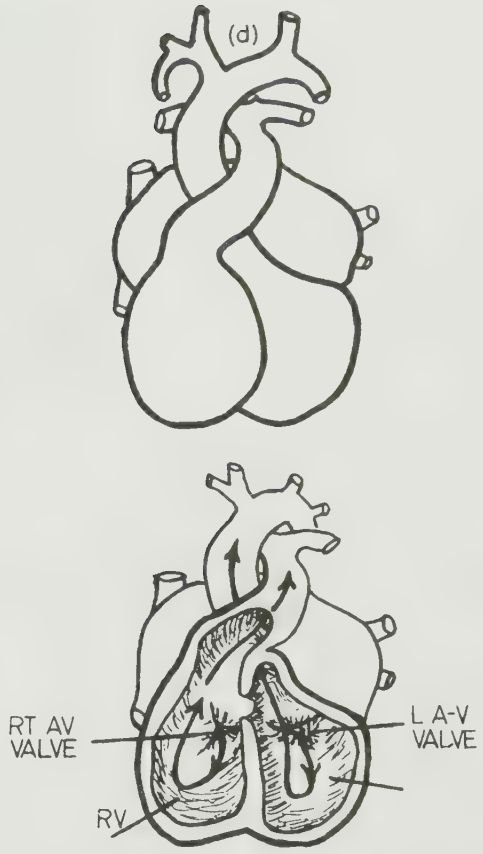

Fig. 73–3. Later stage D-looping of the heart tubes. Upper diagram shows intact heart; lower diagram shows cutaway of the same stage embryologically. The right ventricle now is in apposition to the right-sided systemic veins and right atrium whereas the left ventricle is in apposition to the left atrium and the pulmonary venous system (i.e., atrioventricular concordance).

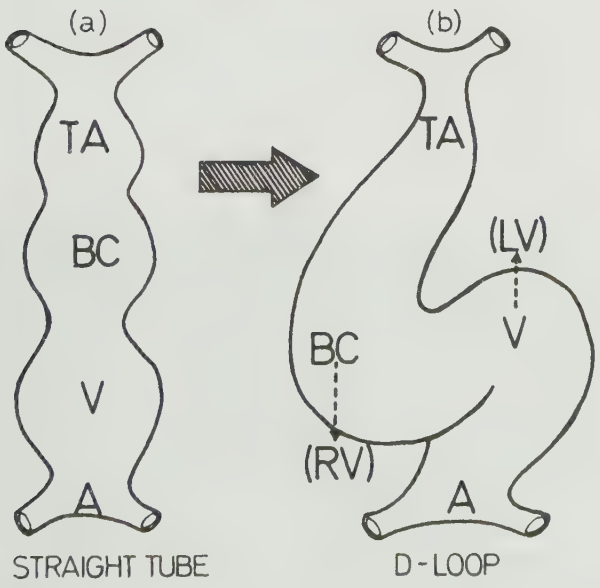

Fig. 73–2. Normal D-looping of the primitive cardiac tube. The bulbus cordis (primitive right ventricle) moves ventrally and to the right in the body, leaving the primitive ventricle (primitive left ventricle) dorsally and to the left in the body.

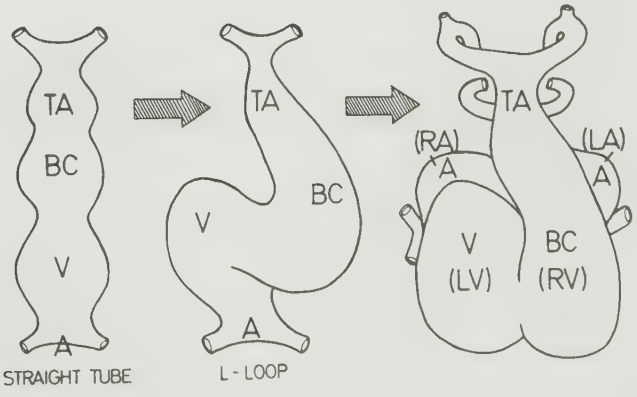

Fig. 73–4. L-looping of the primitive cardiac tube moving the bulbus cordis (primitive *right* ventricle) ventrally and to the left in the body leaving the primitive ventricle (primitive left ventricle) dorsally and to the right in the body.

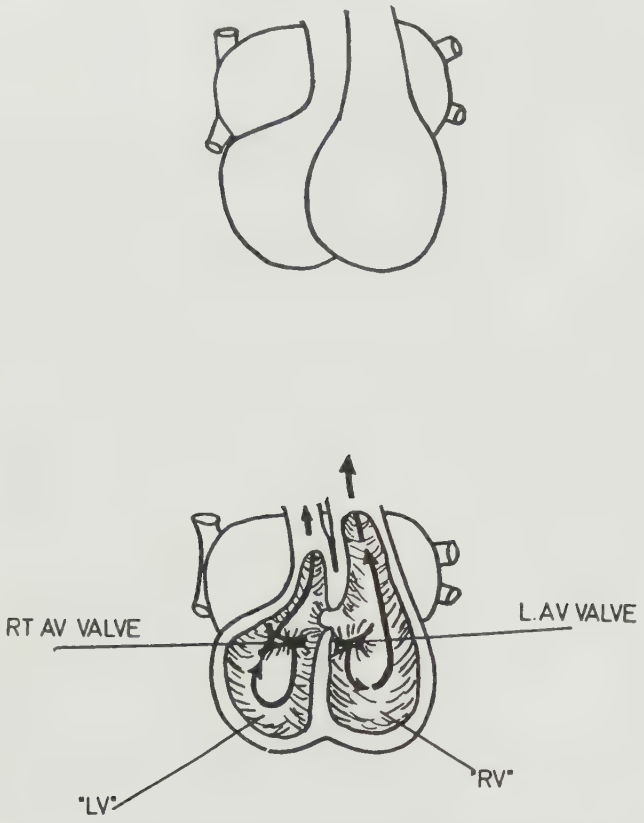

Fig. 73–5. Late stage L-looping of the heart tube. The intact heart (top) and cutaway of the same stage (bottom). The right ventricle, now on the left in the body, is in apposition to the left atrium and pulmonary veins whereas the left ventricle, now on the right in the body, is in apposition to the right atrium and systemic venous system–atrioventricular discordance or ventricular inversion.

result in atrioventricular discordance (ventricular inversion with situs inversus). The embryologic aspects of situs and looping are discussed further in Chapter 75.

The embryology of the great artery relationships and eventual connections is still poorly understood. Usually there is little discussion or at most superficial reference to this important event in the development of the final heart. The truncus is similar to the sinus venosus in that both are originally mesenchymal structures and early in development more associated with the vessels leaving and entering the heart tube respectively than to the heart itself. There is agreement that the truncus divides into the aortic and pulmonary arteries by the ingrowth of mesenchymal ridges and that these ridges, which become the aortopulmonary septum, fuse with the endocardial outlet septum.[14] There is no knowledge or agreement on how this occurs. In the normal heart with normal atrioventricular, or D-loop, embryology and the usual ventriculo–arterial connections, this requires a 180° rotation of the aortopulmonary septum. In transposed great arteries, this rotation does not occur. In ventricular inversion, or L-loop embryology of the heart tube, it seems normal for the rotation of the aortopulmonary septum *not* to occur as though the rotation were more influenced by the looping of the heart tube than by the eventual internal structures of the heart.

ASSOCIATED LESIONS

Normally Connected Great Arteries

Isolated ventricular inversion (atrioventricular discordance), without associated transposition of the great arteries—pulmonary artery arises from the right ventricle (Fig. 73–6) and the aorta from the left ventricle (Fig. 73–7) with ventriculo–arterial concordance—is the rarest "defect" linked with ventricular inversion.[15] It results in the most severe hemodynamic abnormality of any associated defect. The net physiologic effect is the same as that of transposition of the great arteries in association with atrioventricular concordance (nonventricular inversion). Without more associated intracardiac shunt lesions, ventricular inversion with normally connected great arteries results in severe cyanosis and is life-threatening.

The combination of ventricular inversion (atrioventricular discordance) with normally connected great arteries (ventriculo–arterial concordance) also occurs in association with situs inversus of the atria. Thus, the patient has situs inversus of atria, ventricular inversion (atrioventricular discordance) as a result of D-looping, and normally connected great arteries (ventriculo–arterial concordance) (i.e., right atrium to left ventricle to aorta). The patient still has transposition physiology.

Transposition of the Great Arteries

Most cases of ventricular inversion occur with transposition of the great arteries (ventriculo-arterial discordance). In this combination, the right ventricle remains very muscular, becomes more spherical, receives pulmonary venous blood, and pumps to the systemic circulation (Fig. 73–8). The left ventricle, on the other hand, is less muscular, becomes somewhat flattened and wraps partially around the right ventricle, receives systemic venous blood, and pumps to the pulmonary circulation (Fig. 73–9). The resultant circulation is corrected physiologically, and in the absence of other defects can function normally, leading to the synonym of embryologically corrected transposition of the great arteries. However, only 1% of cases of ventricular inversion with transposition of the great arteries do not have other significant associated defects.[16,17]

Ventricular Septal Defect

Next to transposition of the great arteries, the most commonly associated defect with ventricular inversion is a ventricular septal defect. This occurs in approximately 80% of the cases.[18] Any type or location of ventricular septal defects may occur, or multiple types may appear together. The net hemodynamic effect of the ventricular septal defects in patients with ventricular inversion and transposition of the great arteries is identical to that in patients with ventricular septal defects in otherwise normal hearts; it results in shunting from the systemic to the pulmonary circulation. In the patient with ventricular inversion, however, this is shunting from the right ventricle into the left ventricle. Like the ventricular septal defect in patients with otherwise normal hearts, the degree of hemodynamic alteration in these patients is related to a combination of factors, including the size of the ventricular septal defect, the total pulmonary resistance, and the degree of any associated pulmonic stenosis. The majority of patients with ventricular inversion and large ventricular septal defects have associated pulmonic stenosis. As a consequence, very few patients with ven-

Posteroanterior (left) and lateral (right) right ventricular angiocardiograms. The leftward and posteriorly displaced trabeculated right ventricle gives rise to the pulmonary artery. This ventricle is connected to the left atrium and receives fully saturated pulmonary venous blood.

tricular inversion, transposition of the great arteries, and two distinct ventricles develop problems of congestive failure because of the ventricular septal defect. In the absence of any associated pulmonic stenosis, infants with this combination will develop congestive heart failure and/or pulmonary vascular disease similar to conditions in infants who have an isolated large ventricular septal defect in an otherwise normal heart.

Pulmonary Stenosis

Pulmonary stenosis, another commonly associated lesion with ventricular inversion and transposition of the great arteries, usually coexists with the ventricular septal defects. Some degree of pulmonary stenosis occurs in at least 50% of cases, and half of these are significant.[17,19] The pulmonary stenosis is usually subvalvular and results from a bulging of the malaligned ventricular septum and/or actual membranous subvalve excrescences. There are cases of aneurysms of the membranous ventricular septum bulging from the systemic right ventricle into the subpulmonic left ventricular outflow tract causing subpulmonic obstruction.[20] In a few cases, there is actual valve pulmonary stenosis with bicuspid, or even unicuspid, valves. Significant pulmonary stenosis in association with a ventricular septal defect in these patients can result in a "tetralogy" type of hemodynamics with the development of shunting of desaturated blood from the left ventricle into the systemic circulation.

Atrioventricular Valve Abnormalities

Structural abnormalities of the tricuspid valve occur in at least 90% of all patients with ventricular inversion.[18] These abnormalities can be minor, including elongation of the leaflets, or major, such as an Ebstein's type malformation with various degrees of displacement of the valve into the right ventricle.[21] Of the structurally abnormal valves, approximately 30% are functionally abnormal during infancy and childhood. In general, the functional abnormality of the tricuspid valve progresses in individual patients with age, as does the overall incidence of the functional valve abnormalities in patients with ventricular inversion and transposition of the great arteries. When the valve is abnormal functionally, it usually is insufficient; this systemic atrioventricular valve regurgitation often is the major hemodynamic abnormality.

In addition to the specific abnormality of the tricuspid valve, straddling of the ventricular septum of either of the atrioventricular valves can occur with an inlet ventricular septal defect. These valve abnormalities may not have significant or recognizable hemodynamic consequences by themselves and can go undetected. On the other hand, straddling atrioventricular valves may complicate, if not prohibit, eventual corrective surgical procedures.

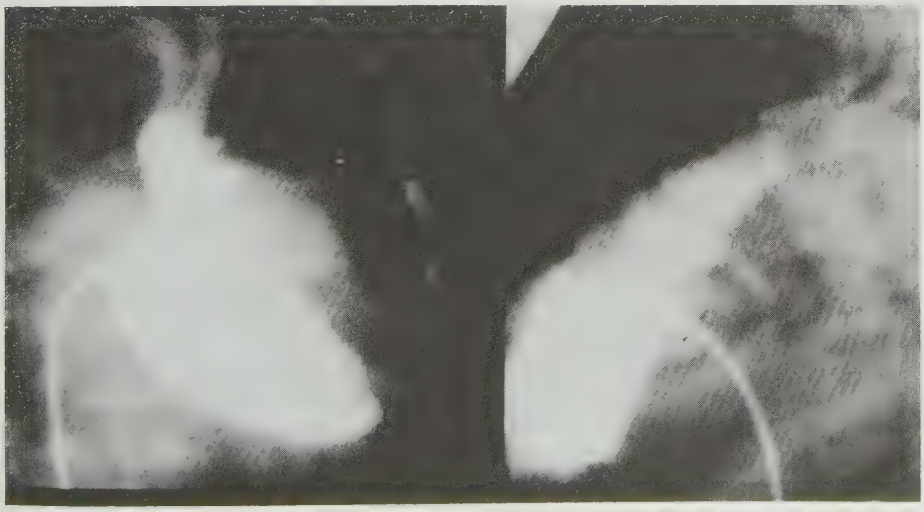

Fig. 73–7. Ventricular inversion with normally connected great arteries and atrioventricular discordance with ventriculo–arterial concordance. Posteroanterior (left) and lateral (right) left ventricular angiocardiograms. The rightward (in the chest) and anteriorly displaced smoother-walled left ventricle gives rise to the aorta (there is some filling of the pulmonary artery through a ventricular septal defect). This left ventricle is connected to the right atrium and receives systemic venous blood (same patient as shown in Fig. 73–6).

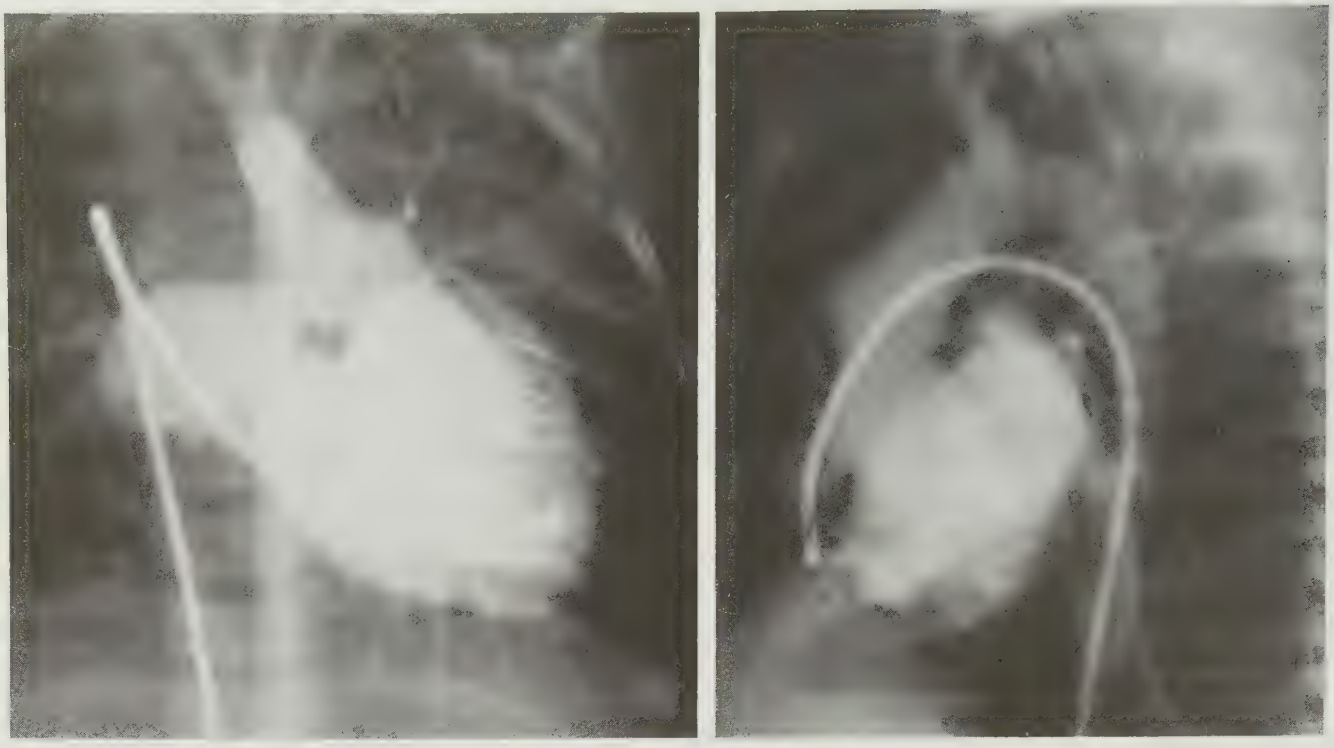

Fig. 73–8. Ventricular inversion with transposition of the great arteries and atrioventricular discordance with ventriculo–arterial discordance. Posteroanterior (left) and lateral (right) angiocardiograms. Recirculation from the lungs shows the left atrium emptying into the right ventricle, which is heavily trabeculated, has a distinct conus, and empties into the aorta.

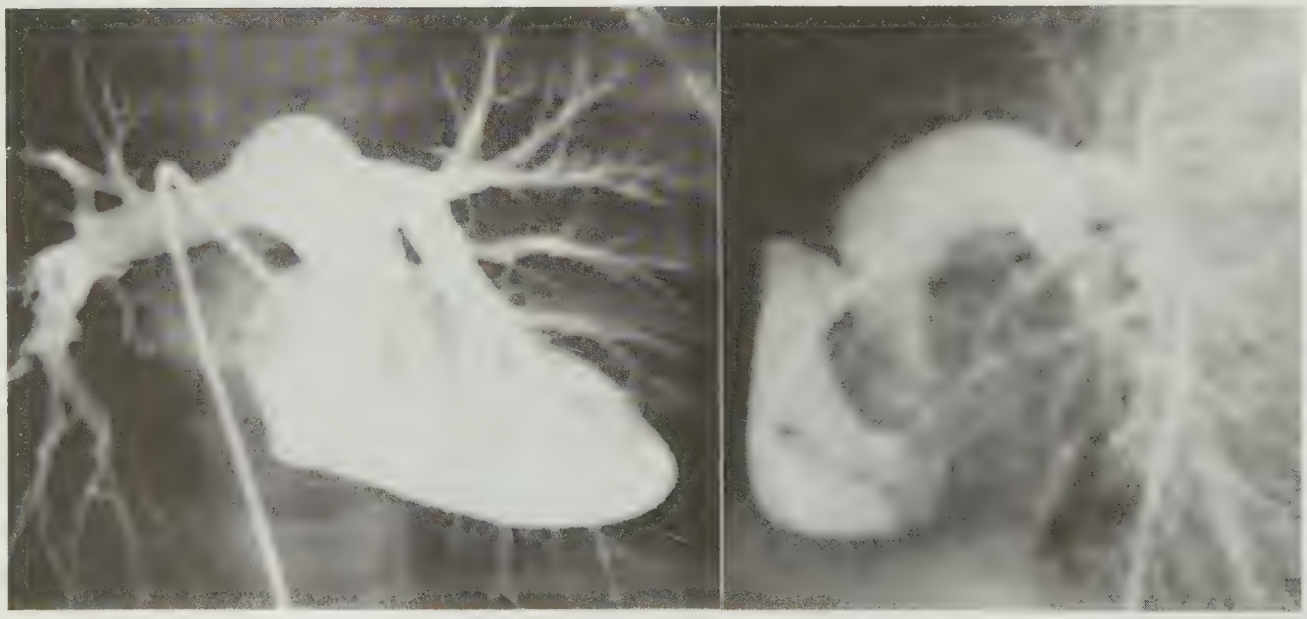

Fig. 73–9. Ventricular inversion with transposition of the great arteries and atrioventricular discordance with ventriculo–arterial discordance. Posteroanterior (left) and lateral (right) angiocardiograms in the smooth-walled, pear-shaped left ventricle which empties into the pulmonary artery. The catheter passage and blood flow are from the right atrium into the left ventricle (same patient as shown in Fig. 73–8).

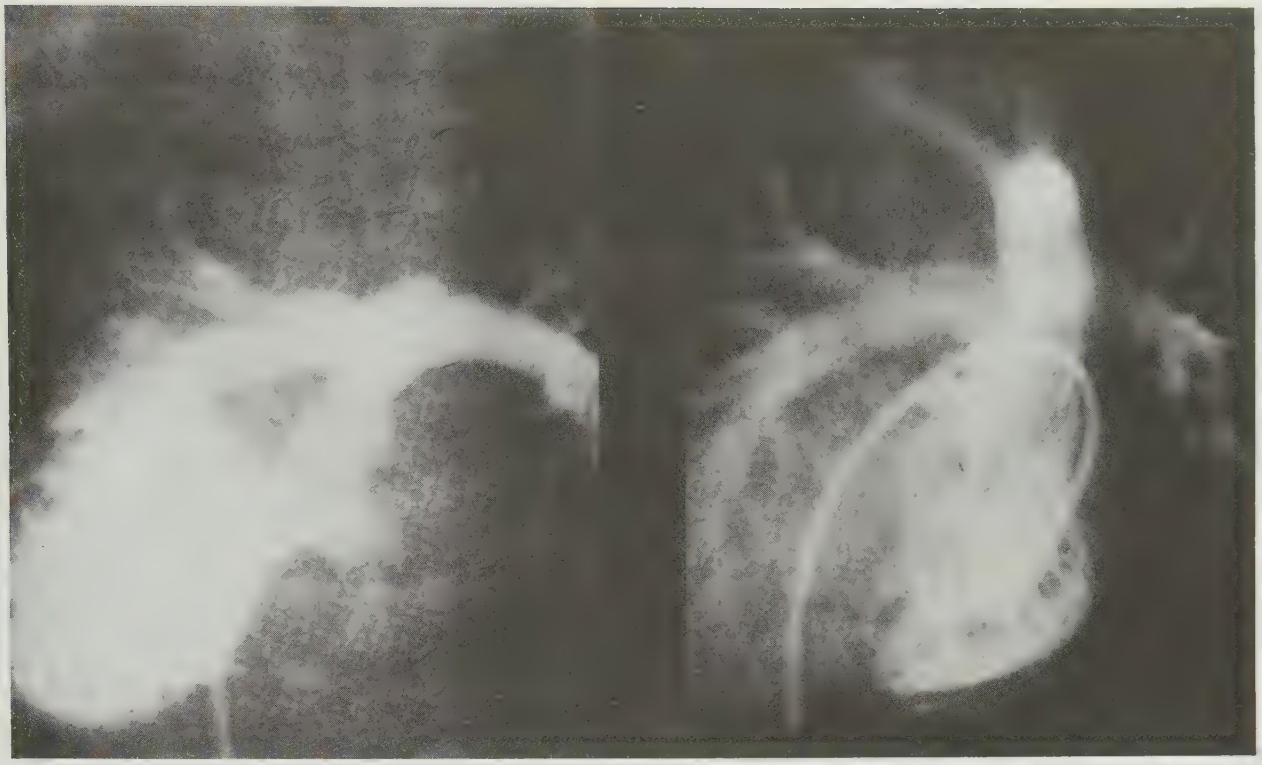

Fig. 73–10. Ventricular inversion, transposition of great arteries, ventricular septal defect, and pulmonary stenosis with dextrocardia and situs solitus of the atria. Posteroanterior angiocardiograms in the left ventricle (left panel) and in the right ventricle (right panel). The left ventricular angiocardiogram cuts the ventricular septum on edge and shows the ventricular septal defect.

Conduction Abnormalities

Because of the atrial to ventricular septal malalignment and the position of the pulmonary valve, the normal AV node does not give rise to a normal AV conduction bundle.[22] Instead, an additional or accessory AV node exists that gives rise to an abnormally positioned atrioventricular conduction bundle. This abnormal bundle penetrates more anteriorly and runs superficially down the anterior septal surface of the left ventricle and pulmonary outflow tract. In the presence of a perimembranous ventricular septal defect, the bundle runs anterior to the defect, or, in the case of less malaligned atrioventricular relations, both the normal and the accessory bundles penetrate into the ventricular septum and straddle the top and bottom of the left ventricular side of the ventricular septal defect. As a result of this precariously positioned AV bundle, naturally occurring AV conduction abnormalities and surgical AV block are common in patients with ventricular inversion. Approximately 10% of these patients present initially with complete AV block.[23] Another 20 to 30% will have first-degree or second-degree AV block initially. This has the tendency to progress to complete AV heart block as patients age.[24] The incidence of complete AV block in older children and adults is as high as 30%. The complete AV block may occur spontaneously even in the absence of earlier lesser degrees of AV block. AV block in patients with ventricular inversion also has been precipitated by anesthesia, cardiac catheterization, or even the thoracotomy prior to any actual cardiac surgery. Because of the associated defects usually present, complete AV block may not be well tolerated; usually, pacemaker therapy is recommended early after the recognition of complete AV block.

Dextrocardia

Dextrocardia with situs solitus (or mesocardia with situs solitus) occurs in approximately 25% of patients with ventricular inversion and transposition of the great arteries.[7,24] The high incidence of this easily detected, frequently associated defect actually should suggest the major underlying ventricular inversion with transposition. This abnormality does not complicate the hemodynamics, however, and may complicate understanding of the hemodynamics. The dextrocardia presumably results from the rightward rotation of the cardiac mass from its embryonic post-L-loop levoposition (opposite to the leftward rotation of the D-loop heart) as it descends into a more thoracic location. During echocardiographic or angiocardiographic evaluation of these patients, the dextrocardia and its effect on the position of the ventricular septum must be recognized. In most patients with this combination and the dextrocardia, the septum lies in a straight anterior/posterior plane and thus is best cut on edge by a straight anterior–posterior projection.

Dextrocardia with situs solitus also will compromise any surgical approach to intracardiac lesions. The rotation of the ventricular mass in front of the right atrium will hinder normal cannulation of the venae cavae and may interfere with a right atrial approach to such structures as the ventricular septal defect.

In addition to dextrocardia, positional abnormalities of the chambers due to peculiarities in rotation during development are

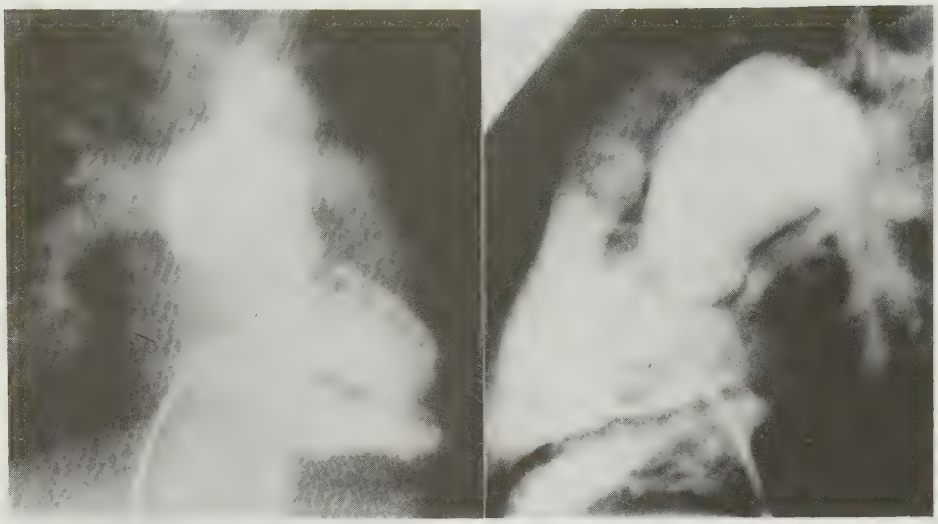

Fig. 73–11. Ventricular inversion, transposition of the great arteries, ventricular septal defect, and pulmonary stenosis with associated cephalocaudal (''upstairs-downstairs'') relationship of the ventricle. Posteroanterior (left) and lateral (right) angiocardiogram in the more cephalad right ventricle fills the aorta but also, through the ventricular septal defect, the left ventricle and pulmonary artery.

common with ventricular inversion and transposition of the great arteries. Because of the relative positions of the ventricles to each other, these abnormally positioned hearts are sometimes referred to as ''upstairs-downstairs'' hearts or, because of the resultant twisted pathways of the atrioventricular connections, they are called ''crisscross'' hearts (Figs. 73–11 and 73–12). Although these terms help to identify the relative positions of the chambers, they do not clarify the exact anatomy and physiology. Since these positional abnormalities may occur with normal atrioventricular and ventriculo–arterial connections, the positional terminology must be used only in conjunction with the precise definition of the more important atrioventricular and ventriculoarterial connections and not as total diagnoses.

Rudimentary Ventricular Chamber

At least 75% of univentricular hearts with a double inlet left ventricle are ventricular inversions with transposition of the great arteries. These hearts usually are not included in the discussion of ventricular inversion but are in the large category of univentricular hearts. The basic embryology of a double inlet left ventricle is that of L-looping of the cardiac tube; in addition, these hearts have underdevelopment of the bulbus cordis into a right ventricle and along with this, an absent or incomplete migration of the atrioventricular valve toward the right ventricle. As a result, the sinus portion of the right ventricle is absent or markedly underdeveloped, and both atrioventricular valves empty into the left ventricle. With partial development of the right ventricle and partial migration of the valve, there will be straddling of the tricuspid valve. The one constant relationship in these hearts is that the right atrium empties into the left ventricle, thus meeting the criteria for atrioventricular discordance or ventricular inversion. As the name implies, these lesions represent types of single ventricle or univentricular heart and are included in Chapter 74.

Coronary Arteries in Ventricular Inversion and Transposition of the Great Arteries

The coronary arteries have the usual ''right'' and ''left'' morphology and follow a distribution appropriate for the *ventricles* arising from the aortic valve sinuses adjacent to the appropriate ventricle. The morphologic left coronary artery arises from a right-sided/posterior sinus and courses anteriorly and rightward over the left ventricle and anterior to the pulmonary valve ring, giving rise to the anterior descending and circumflex branches. The anterior descending artery courses further anteriorly in the interventricular

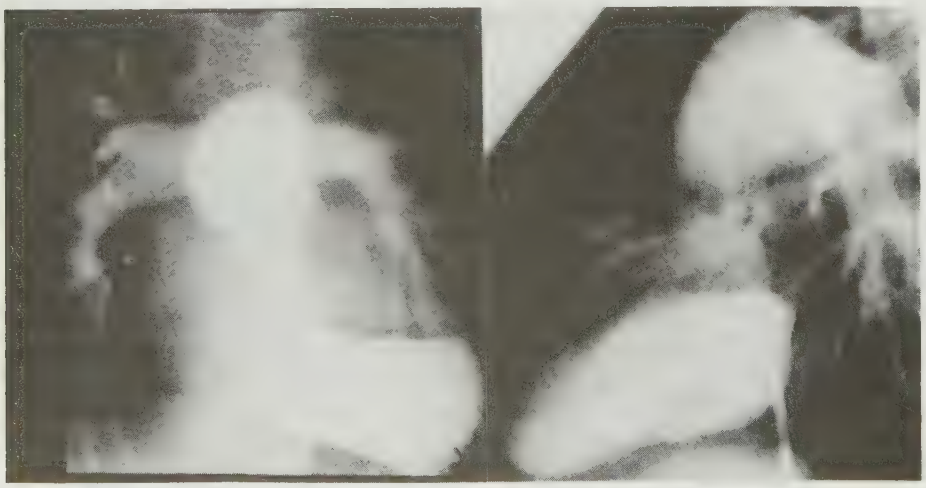

Fig. 73–12. Ventricular inversion, transposition of the great arteries, ventricular septal defect, and pulmonary stenosis with associated cephalocaudal (''upstairs-downstairs'') relationship of the ventricles (same patient as shown in Fig. 73–11). Posteroanterior (left) and lateral (right) angiocardiogram in the smoother-walled more caudal left ventricle fills predominantly the pulmonary artery.

groove, whereas the circumflex artery passes posteriorly and rightward around the atrioventricular groove of the mitral valve. The morphologic right coronary artery arises from a left-sided/posterior sinus and runs posteriorly over the right ventricle in the atrioventricular groove of the tricuspid valve to become the posterior descending artery. The most common coronary abnormality is a single coronary artery that arises from the right-sided/posterior sinus.[25,26] By itself, the coronary artery anatomy in ventricular inversion does not result in any functional abnormality but may complicate surgical approaches to associated defects with this lesion. The course of the left anterior descending coronary artery crosses over the anterior surface of the left ventricular outflow tract and represents an additional deterrent to a direct surgical approach to left ventricular outflow tract obstruction or a left ventricular approach to a ventricular septal defect.

HEMODYNAMICS AND PHYSIOLOGY

The hemodynamics and physiology of ventricular inversion depend entirely on the associated defects. When associated with transposition of the great arteries and no other abnormalities, ventricular inversion presents a truly ''corrected'' physiologic situation. The systemic venous blood returns to the right atrium, from there goes through the mitral valve into the left ventricle and then passes out into the pulmonary artery. After passing through the lungs, the pulmonary venous blood enters the left atrium. From the left atrium, the pulmonary venous blood passes through the tricuspid valve and into the right ventricle and from there into the aorta. With no associated shunts or obstruction, the pressures and saturations in the appropriate physiologic chambers and great vessels will be normal.[27]

Since most of the patients have associated ventricular septal defects with or without pulmonary stenosis, these lesions cause the major hemodynamic abnormalities. The effect of the ventricular septal defect will be a left-to-right shunt from the systemic to the pulmonary circulation. Although the ventricular septal defect is commonly associated with ventricular inversion and transposition, these patients rarely require early surgical intervention because of pulmonary overcirculation. In most cases, this is because of the associated pulmonary stenosis which, although seldom severe, is usually sufficient to ''protect'' the pulmonary vessels from overcirculation. The net physiologic effect of pulmonary stenosis with the ventricular septal defect in patients with ventricular inversion and transposition of the great arteries depends on the relative severity of the pulmonary stenosis and ventricular septal defect. In most cases, these two associated lesions achieve a relatively balanced situation with neither pulmonary overcirculation from too little pulmonary stenosis nor marked cyanosis from a severe pulmonary stenosis. The other interesting phenomenon with this combination of lesions (which is hemodynamically similar to tetralogy of Fallot) is that unlike the patient with tetralogy, the pulmonary stenosis in ventricular inversion, transposition and ventricular septal defect does not seem to progress to cyanosis but remains in the hemodynamic balance allowing nearly normal pulmonary flow.

The presence of tricuspid (left atrioventricular) valve incompetence often represents a more urgent and more progressive lesion.[10,28] The effect on the right ventricle's capability to function as a systemic ventricle is compromised more by this insufficiency than is a normal left ventricle with mitral valve regurgitation in an otherwise normal heart.

The presence of, or development of, complete atrioventricular block may be tolerated in the absence of other associated lesions or even in the presence of a balanced combination of ventricular septal defect with pulmonary stenosis. However, this tolerance appears less than in an otherwise normal heart; often, the moderately low ventricular rate will necessitate in a pacemaker.

Rarely a patient with isolated ventricular inversion (atrioventricular discordance) and normally connected great arteries (ventriculo–arterial concordance) presents hemodynamically exactly as the infant with noninverted ventricles (atrioventricular concordance) and associated transposition of the great arteries (ventriculo–arterial discordance).[29] These infants with isolated ventricular inversion are markedly cyanotic and like their counterparts, their degree of cyanosis and likelihood of survival depend upon the associated lesions.

CLINICAL FEATURES

The clinical features of ventricular inversion depend almost entirely on the associated defects.[6,30]

History

The extremely rare patient with isolated ventricular inversion and normally connected great arteries presents very early with marked cyanosis and acidosis. With an associated ventricular septal defect or other areas for mixing, the presentation may be slightly later, with more congestive heart failure and less cyanosis.

The patient with ventricular inversion with transposition of the great arteries and no other associated defects may not actually present to a cardiologist but rather be discovered as an adult on a routine physical examination or because of an abnormal chest roentgenogram. Occasionally, these patients, at any age, are detected because of a slow heart rate due to complete atrioventricular block.

In the large majority of patients with ventricular inversion and transposition of the great arteries and associated defects, the patients will present as young infants with a heart murmur and/or evidence of congestive heart failure. The rare infant with severe pulmonary stenosis and associated ventricular septal defect will present with cyanosis.[31,32]

Physical Examination

As with the hemodynamics and history, the physical examination depends predominately on the associated defects.[33] Unless there is associated severe pulmonary stenosis, most of these patients will be acyanotic. Even with ventricular septal defects or ventricular septal defects with pulmonary stenosis, there may be little or no distress. The one finding characteristic of ventricular inversion with transposition of the great arteries is the presence of a very loud, even palpable, single, second heart sound along the upper left sternal border.[33–35] This finding would otherwise suggest transposition in a cyanotic patient or very severe pulmonary hypertension in an acyanotic patient. Any murmurs and/or associated thrills on physical examination result from the associated lesion and usually are characteristic of the hemodynamically dominant associated lesion (i.e., ventricular septal defect, pulmonary stenosis, or tricuspid valve insufficiency).

Chest Roentgenogram

The roentgenogram, as with the other clinical findings, reflects not only the ventricular inversion with transposition but the associated defects. Characteristically, in patients with ventricular inversion and transposition of the great arteries, the upper left heart border is straightened corresponding to the leftward displacement of the ascending aorta.[36,37] In the absence of other significant defects or with the balanced ventricular septal defect and pulmonary stenosis, the heart size is normal as are the pulmonary vascular markings.[38] The presence of mesocardia or, in particular, dextrocardia with a straightened upper left heart border should suggest ventricular inversion with transposition.[39,40] In the presence of a large systemic to pulmonary shunt due to a ventricular septal defect, there will be cardiomegaly and increased pulmonary vascular markings.[30] There also may be significant cardiomegaly in the presence of left AV valve regurgitation.

Electrocardiogram

The electrocardiogram may give the most significant clue to the diagnosis of ventricular inversion. The presence of reversed septal depolarization[41] (i.e., Q waves over the right precordium with absent Q waves over the lateral precordium in the presence of any degree of AV block) but, in particular, complete heart block should immediately suggest ventricular inversion.[17,42] The particular reversal of septal depolarization in the absence of other electrocardiographic criteria of right ventricular hypertrophy also is highly suggestive of this defect.[9,41,43] As with the other clinical features, the associated defects may affect the electrocardiogram and make the diagnosis less obvious.[44]

Echo/Doppler

The advent of two-dimensional echocardiography with interfaced pulsed and continuous wave Doppler ultrasound has improved the accuracy of the noninvasive diagnosis of ventricular inversion and its associated abnormalities substantially. The echocardiographic examination of these patients should be performed in a sequential manner, with identification of the relation and connection of each cardiac segment.[10]

Several major anomalies should alert the echocardiographer to the presence of ventricular inversion. First, there is difficulty in alignment of the intracardiac structures in the usual echo views. In patients with ventricular inversion, the positioning of the heart within the chest and the relationship of the ventricles to each other differs considerably from normal.[45] Additionally, there is discontinuity between the left AV valve and the aortic or left-sided semilunar valve.[10,46] Another prominent feature of atrioventricular discordance is attachment of the left AV valve more inferiorly along the ventricular septum than the right AV valve. This feature is often thought of as the echocardiographic hallmark of atrioventricular discordance but may not be demonstrable if an inlet ventricular septal defect is present, as occurs in many cases.

Other echocardiographic criteria are useful in distinguishing ventricular and AV valve morphology. When chordal attachments of an atrioventricular valve to the inlet septum are present, that atrioventricular valve is almost invariably a tricuspid valve, and the ventricle into which it empties is the right ventricle. Demonstration of such chordal attachments is helpful in confirming that a ventricle is indeed the right ventricle.[45] Conversely, the absence of such attachments indicates that the atrioventricular valve in question is a mitral valve and that the ventricle to which it connects is a left ventricle.

The presence of a left ventricle is suggested by an inlet valve with a bicommissural or "fishmouth" appearance, two discrete papillary muscles, fine trabeculations, and an ellipsoid shape. The presence of a right ventricle is suggested by an inlet valve with a triangular (tricommissural) appearance, multiple irregular papillary muscles, a coarse trabecular pattern, and a roughly triangular shape.

The abnormal atrioventricular connections can be clarified once the ventricular morphology has been identified. Finally, the abnormal relative relationship of the two semilunar valves to each other in these patients and the abnormal course of their great arteries should be demonstrated to support the diagnosis of ventricular inversion with transposition of the great arteries. Obtaining multiple short-axis cross sections through the ventricular outflow tracts is an effective way to demonstrate their orientation and the course of the great arteries.

Many malformations associated with atrioventricular discordance can be shown echocardiographically. Particular attention should be given to evaluation for ventricular septal defects, for pulmonary valve and subvalvular obstruction, and for displacement of the tricuspid valve into the right ventricle. The location and size of ventricular septal defects can be estimated by direct imaging. Two-dimensionally directed pulsed and color Doppler are often helpful in this assessment. Continuous-wave Doppler can assist in estimation of pressure gradient across ventricular septal defects and across the left ventricular outflow tract. Displacement of the tricuspid valve into the right ventricle is visualized readily with two-dimensional echocardiography, and associated valvular insufficiency can be detected by pulsed and continuous-wave Doppler. When multiple defects are present (such as ventricular septal defect and pulmonary stenosis), Doppler studies, particularly continuous-wave Doppler, should be interpreted cautiously. Detailed echocardiographic studies are often helpful in determining when further and more definitive studies will be indicated, particularly if the symptomatology suggests surgical intervention.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis depends upon the associated defects. A patient with ventricular inversion, transposition of the great arteries, and no other defects may appear normal for years.[7,10,27] Even so, physical examination should raise suspicions of some abnormality and suggest the possibility of pulmonary hypertension because of the loud single second heart sound.[30]

In the rare infant who presents with ventricular inversion and normally connected great arteries, the presentation is one of severe cyanosis and is similar to that of infants with transposition of the great arteries with normal atrioventricular relations.[29,47] Isolated ventricular inversion is so rare, it probably should not be considered until at least the echocardiogram or catheterization data are available.

More often, patients present with the findings of a somewhat atypical ventricular septal defect or ventricular septal defect with pulmonary stenosis.[24] The loud second heart sound always suggests associated pulmonary hypertension. The peculiar electrocardiogram and often unusual roentgenogram should immediately sug-

gest the ventricular inversion/transposition complex in addition to the more usual lesions.

CARDIAC CATHETERIZATION

Although the diagnosis should be suspected from the clinical findings and many of the details of the associated defects described by echocardiography, the definitive diagnosis in ventricular inversion regardless of associated defects should be by cardiac catheterization with high-quality selective cineangiocardiograms. Catheterization should aim to acquire all the minute details of the anatomy and precise hemodynamics—not just to verify or identify the general anatomy and basic associated defects. Prior to catheterization of these patients, one should devise a plan of what data are needed and ways to obtain these data. If one undertakes the catheterization of these patients, it should be with the idea that all chambers and vessels will be entered and valid measurements of pressure and oxygen saturation obtained from each location.

The difficulty in entering the pulmonary artery by the usual manipulations with the catheter and the catheter course once one has entered a great artery immediately suggest ventricular inversion—even in the unlikely situation in which it was not suspected before catheterization. The catheter passage from the right atrium to the left ventricle is relatively easy and similar to the maneuver in the normal heart. But the similarity ends here. There is an approximate 180° turn from the inflow of the left ventricle to the outflow into the pulmonary artery with the outflow directed medially and posteriorly to the patient's right. Often with an associated ventricular septal defect, the usual "right heart" catheter manipulations will result in the catheter's passing through the ventricular septal defect and into the ascending aorta. Because of the peculiar angle into the pulmonary artery and problems with the conduction system to be mentioned later, in this situation the use of a diagnostic floating balloon catheter may be indicated as the initial catheter for the study.

With the high probability of tricuspid valve abnormalities, the left atrium must be entered both for hemodynamic measurements across this valve and for high-quality angiography in the left atrium. Fortunately, the atrial relationships to each other and the interatrial septum are relatively normal so that a standard transseptal approach makes entry into the left atrium very straightforward should the patient have an intact atrial septum.

Angiocardiography

High-quality, selective angiocardiograms provide the essential definitive anatomic information in these patients.[48] The basic anatomy is demonstrated best by selective ventricular angiocardiograms in each ventricle using at least 1 cc/kg of contrast delivered in one heart beat. If an associated ventricular shunt lesion is suspected or known, twice this much contrast may be necessary. Because of the peculiar abnormal orientation of the interventricular septum in these patients, the best initial view is in the straight posterior–anterior and lateral projections. This will usually cut the ventricular septum on edge and, if there is a ventricular septal defect, outline it well. The posterior–anterior projection will define the right ventricle and separate the inflow and outflow areas of the ventricle. The left ventricle is stretched out almost in its longest dimension in this view. If, in any particular patient, some additional peculiar orientation of the anatomy is noted on the first angiocardiogram, then adjustment and modification of the projections to best suit the individual patient must be made on the basis of the original injection and not on previously prescribed angled views.[10,49]

The ventricular angiocardiograms should provide valuable information about the AV valves and suggest the ideal projections to use for more selective atrial angiocardiograms to look at these valves.

Extra Risks to Cardiac Catheterization

With ventricular inversion, the AV conduction system is more "fragile" than in hearts with normally related ventricles. Structurally, the common AV bundle remains on the left ventricular side of the septum immediately beneath the pulmonary valve; in this case of the commonly associated ventricular septal defect, the conduction system courses anteriorly around the upper rim of the septal defect. This places the already-fragile bundle in a precarious position on the "working" side of the usual right heart catheterization and directly in the path of the catheter tip as it is manipulated anteriorly and cephalad toward the outflow tracts. Complete and permanent heart block has occurred with the first manipulation of the catheter from the right atrium into the left ventricle, and at least transient complete heart block occurs commonly following any manipulation in the left ventricle. To minimize trauma in the region of the outflow tract, the use of a floating balloon catheter during the manipulations of the diagnostic "right heart" catheterization is recommended.

Therapeutic Catheterization

The rare newborn infant with ventricular inversion and normally connected great arteries, like the infant with transposition of the great arteries and atrioventricular concordance, has transposition physiology with parallel pulmonary and systemic circulations. Similarly, these infants are dependent upon intracardiac mixing through some additional defect for survival and, in the absence of a preexisting atrial septal defect, should undergo an emergency balloon atrial septostomy.

MANAGEMENT

No therapy is necessary for the patient with ventricular inversion and transposition of the great arteries and no other cardiac defect. These extremely rare patients are corrected physiologically and have been reported to have near-normal life expectancy. However, most cases of ventricular inversion with transposition have other associated defects, which often require earlier therapeutic intervention.

Conservative

The management of these patients should be predicated predominantly on symptoms rather than the theoretical improvement that might be made in their hemodynamics. In determining therapy, one should always be reasonably sure that the patient will be *symptomatically* improved by the therapy. This is because the surgical approach is more difficult, frequently leading to a poor hemodynamic result; also, complete heart block is very likely to result. The exception to this rule is when there is significant objective deterioration in the functional capacity of the heart that has not yet caused overt symptoms or when there is a potentially life-

threatening situation. Examples of this would be progressive right ventricular dilation and decreased right ventricular function due to left AV valve insufficiency yet no overt symptoms of pulmonary congestion or "left-sided" heart failure, or complete AV block with a very slow ventricular response yet not causing syncope. The patient with a ventricular septal defect and markedly elevated pulmonary artery pressures that would probably lead to pulmonary vascular disease would require surgical intervention.

Surgical

There probably should be no elective surgery for the defects associated with ventricular inversion and transposition of the great arteries. Although better results recently have been reported,[50] these address primarily survival of the surgery rather than long-term functional improvement. Surgical therapy of even the simple but commonly associated defects such as the ventricular septal defect or the pulmonic stenosis carry a much higher surgical morbidity (and even mortality) as well as even higher likelihood of being unsuccessful in improving functional capacity.

Although the ventricular septal defect is usually in the perimembranous location, surgery is hampered by lack of any direct approach to the defect. Because the right ventricle serves as the systemic ventricle, one should not open this chamber. A ventriculotomy into this chamber creates damage to this already embryologically compromised systemic ventricle. The left-sided atrioventricular tricuspid valve usually is abnormal congenitally and, as a result, is marginally effective as a systemic atrioventricular valve as well. It also connects the *left* atrium with the right ventricle, making the technical considerations to any approach to the ventricular septal defect through the tricuspid valve difficult if not impossible. The recommended approach to the ventricular septal defect is through the mitral valve, either by displacing the septal leaflet or, more often, incising the mitral valve at the annulus to approach the ventricular septal defect and then resuturing the mitral valve after the ventricular defect is closed. In addition to the difficult exposure and potential for permanent mitral valve damage, this approach places the surgery on the AV node side of the septum, requiring that the patch on the ventricular defect be sewn through the defect on the opposite, or right ventricular, side of the septum.[51,52] Even this difficult approach frequently does not protect the AV node and conduction system, and AV block results.

The pulmonary stenosis creates an even greater problem.[53] The stenosis is usually subvalvular; this area is relatively posterior within the heart, with the right ventricle overlying it anteriorly and to the left and the anterior leaflet of the mitral valve guarding the area from the right approach. In addition, the AV conduction system runs in this vicinity on the left ventricular side of the septum and even tension on the valve apparatus before any surgical excision of tissue has produced atrioventricular block. Experience has been so poor with any direct approach to this area that the accepted approach to the subvalve pulmonary obstruction now is by an interposition conduit from the apex or wall of the left ventricle to the pulmonary artery.

Indications for tricuspid valve replacement in patients with ventricular inversion are similar to those for mitral valve replacement in a patient with normal atrioventricular connections.[53] Technical problems of a proper valve insertion are similar to those in the Ebstein's malformation of the tricuspid valve in patients without ventricular inversion and are further indication to delay this surgical procedure for as long as possible without compromising right ventricular function.

The rare patient with ventricular inversion and normally connected great arteries, ironically, is the best candidate for surgical correction. A standard venous switch (Mustard or Senning) procedure performed early will physiologically and almost anatomically correct these patients by redirecting the systemic venous blood into the right ventricle, which gives rise to the pulmonary artery, and redirecting the pulmonary venous blood into the left ventricle, which opens to the aorta. This is the only situation in which relatively early and elective surgery should be considered in patients with ventricular inversion.

CHAPTER 74

Single Ventricle

Edward V Colvin

This chapter concerns a group of hearts unified by certain similarities and divided by significant differences. Controversy persists concerning which similarities should allow inclusion of an individual heart within the group, which differences should be used for subclassification, and which terms are most useful in describing the hearts.

Case reports in the 1800s and earlier drew attention to the existence of hearts with one large chamber in the ventricular mass. Often a second, much smaller chamber was recognized. An interesting anecdote in the history of pediatric cardiology centers around a case of a single ventricle. The new curator at the medical museum of the McGill Medical School in Montreal, Dr. Maude Abbott, wrote the former curator with questions about the unusual specimen with only one ventricle. Dr. William Osler answered that the specimen was from a 22-year-old man who had had moderate cyanosis since childhood that increased on exertion. The man had episodes of chest pain with shortness of breath and died during one of these episodes. Dr. Osler indicated that the case had been reported by Dr. Andrew F. Holmes, the first dean of the medical faculty of McGill University. Dr. Osler encouraged Dr. Abbott to report the "Holmes heart" again and to write the section on congenital cardiac disease in his famous textbook, *The Principles and Practices of Medicine*. This unusual single-ventricle specimen began the career of Dr. Abbott in the study of congenital heart disease, which was instrumental in the development of the field of pediatric cardiology. The "Holmes heart" is discussed later in this chapter.

Over the years various names have been applied to such single-ventricle hearts[1,2] (Table 74–1). Despite the fact that in most of these hearts there were two chambers within the ventricular mass, "single ventricle" became the most commonly used name.[3]

In 1964, Van Praagh, Ongley, and Swan[4] described a group of these hearts. The criteria for inclusion was the presence of a chamber receiving either both tricuspid and mitral valves or a common atrioventricular valve. Hearts with tricuspid or mitral atresia were specifically excluded. The terms single ventricle and common ventricle were used interchangeably but frequently the presence

Apparently single ventricular chamber
Double-inlet right ventricle

After Van Praagh, R., Plett, J.A., Van Praagh, S.: Single ventricle: Pathology, embryology, terminology, and classification. Herz, *4*:113–150, 1979.

of an outlet chamber was acknowledged. Hearts were divided into types A through D according to ventricular morphology, and subdivided into groups I through IV according to the relative positions of the arterial valves (Fig. 74–1). "The principal ventricular malformation in each type is absence of the right ventricular sinus (type A); absence of the left ventricular sinus (type B); absence, or rudimentary development, of the sinus portion of the ventricular septum (type C); and absence of both right and left ventricular sinuses, and hence, also of the ventricular septum (type D)."[4] The relationships between the great arteries were described as normal (type I), d-transposition (type II), l-transposition (type III), and inversus (type IV). The most common form of single ventricle would be called type A III. Lev et al.[5] reported a second series of hearts, accepting the definition of single ventricle on the basis of the entrance of both atrioventricular valves or a common valve into a single ventricle.

Other authors pointed out the similarity within the ventricular mass of hearts classified as single ventricles and other hearts excluded from this grouping because of an absent or imperforate right or left atrioventricular (AV) valve.[6–10] Surgical techniques developed for separating the systemic and pulmonary circulations in tricuspid atresia[11,12] were successfully applied to hearts with right and left AV valve atresia and to hearts fitting Van Praagh's definition of single ventricle.[13]

Because of the similarities in ventricular architecture and surgical intervention, it became desirable to group these hearts together. An attempt to do this[14] while preserving the standard English meaning of "single" in the term "single ventricle" led one group to redefine the term "ventricle," ascribing ventricular status to a chamber with inlet and trabecular components, while denying ventricular status to (sometimes larger and more well-formed) chambers with only apical trabecular and outlet components. To deal with the hearts in which an atrium was connected to more than one chamber in the ventricular mass (overriding atrioventricular valves) a 50% rule was applied. When an atrium was connected partly to one chamber and partly to another, the inlet was assigned to the chamber in the ventricular mass connected to greater than 50% of the atrium. Thus, a chamber receiving 49% of an atrioventricular orifice was not a ventricle, whereas one receiving 51% was. This violated one of the fundamental precepts of the morphologic method of nomenclature, that each structure should be named according to its own morphology and not according to adjacent structures. Confronted[15,16] with the implications of this redefinition of a ventricle, Anderson et al.[17,18] abandoned this tactic and recognized that they were defining a grouping on the basis of a different selection criterion.

Rather than focusing on the ventricular anatomy they focused on the atrioventricular connection. By this new criterion, a heart is included in the grouping (hearts with univentricular AV connection) if both atria are connected to a single chamber within the ventricular mass. Thus, most hearts classified by Van Praagh as members of the single ventricle group are included, but now the hearts in which both atria connect to a single chamber are included even if one valve is imperforate or atretic. Hearts in which each atrium is connected to its own ventricle are excluded even if one of the valves is atretic or imperforate. These hearts are included in the group of hearts with biventricular AV connection.

In this chapter we will discuss this larger group of hearts defined by the presence of an univentricular AV connection. Tricuspid atresia and mitral atresia will also be discussed in more detail in other chapters.

RELATIONSHIPS BETWEEN THE GREAT ARTERIES

Type	I	II	III	IV
Superior / Right ↔ Left / Inferior / Anterior View	Normal	D-Transposition	L-Transposition	Inversus
Posterior / Right ↔ Left / Anterior / Superior View

Fig. 74–1. Subclassification of 60 hearts with single ventricle. Ao = aorta; PA = pulmonary artery; AoV = aortic valve; PV = pulmonary valve; RV = right ventricle; LV = left ventricle; Inf = infundibulum; RVM = RV mass; LVM = LV mass. (From Van Praagh, R., Ongley, P.A., and Swan, H.J.C.: Anatomic types of single or common ventricle in man: Morphologic and geometric aspects of 60 necropsied cases. Am. J. Cardiol., *13*:367, 1964.)

NOMENCLATURE

Atrial Situs and Atrioventricular Connection

The segmental approach to nomenclature[19–23] is necessary to describe these hearts. Atrial situs may be solitus or inversus, or there may be atrial isomerism, with bilateral right or left morphology. The axis of the ventricular mass may be leftward (levocardia), rightward (dextrocardia), or midline (mesocardia). The type of atrioventricular connection is, by definition, univentricular. The mode of connection may be double inlet, absent left, or absent right atrioventricular connection. In double inlet the two atria may be connected to the ventricle by means of two separate valves or via a common valve (Fig. 74–2). When two separate valves are present, they usually do not have typical characteristics of mitral and tricuspid valves[5] and are therefore referred to as right and left on the basis of the anatomic location of the atrium to which they are connected. Either of these valves may be stenotic or even imperforate. Since both atria are connected to one ventricle, the connection cannot be termed concordant or discordant.

When one atrium lacks a connection to the ventricles, it is difficult to be certain whether the missing valve would have been mitral or tricuspid. We prefer to use the terms absent left and absent right AV connection to describe these hearts.[24–33]

Hearts with two valves, each connecting an atrium to its own ventricle, are considered to have biventricular atrioventricular connection, even if one of the valves is imperforate. Hypoplastic left

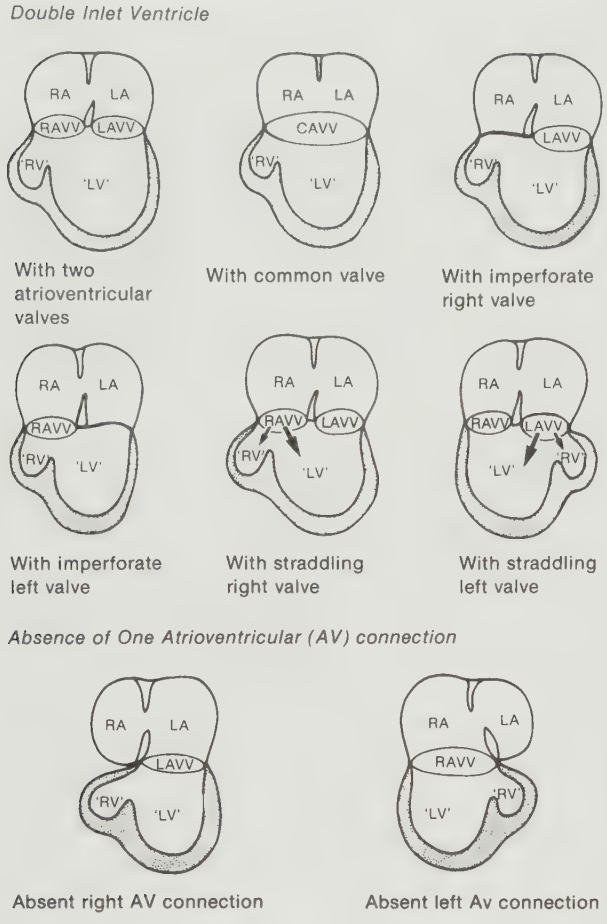

Fig. 74–2. The modes of atrioventricular connection found in a series of hearts with dominant left ventricle. RA = right atrium; LA = left atrium; RAVV = right atrioventricular valve; LAVV = left atrioventricular valve; RV = right ventricle; LV = left ventricle. (From Anderson, R.H., et al.: Ventricular morphology in the univentricular heart. Herz, *4*:184, 1979.)

heart syndrome, in which a hypoplastic or imperforate left AV valve connects the left atrium to a small left ventricle (usually in association with aortic atresia), is excluded from the group of hearts with univentricular AV connection. In pulmonary atresia with intact ventricular septum, there is one large and one small ventricle. Since the AV connection is biventricular, these hearts are also excluded from this grouping.

In any system of nomenclature one must decide how to deal with hearts in which the atrial myocardium is connected to more than one ventricle (overriding of the AV valve annulus) and with hearts in which the tensor apparatus of the AV valve enters both ventricles (straddling). One could consider this a special type of atrioventricular connection and group these hearts as having neither univentricular nor biventricular AV connection.[34,35] Practically, they must be treated by the surgeon as he would treat hearts with univentricular or biventricular connection. The degree of overriding determines the type of connection. By the 50% rule, if more than 50% of the AV connection overrides and connects to the opposite ventricle the connection is considered to be univentricular, otherwise a biventricular connection is said to be present. If straddling of the tensor apparatus is present, the degree must be specifically stated, as this is an important surgical detail.[36] When there is atresia of one valve the remaining valve may straddle.[37] Part of a common valve may straddle. When two AV valves are present, one or conceivably both may straddle.

Ventricular Architecture

In embryologic terms, a complete ventricle has sinus and infundibular (or conus) portions. The embryologic origin of the sinus portion of the right ventricle remains controversial. Use of these terms to describe the ventricular anatomy requires speculation as to the embryologic origin of the different chambers. In more descriptive morphologic terms, a complete ventricle may be said to have inlet, apical trabecular, and outlet components.[38] The inlet component comprises the portion downstream from the atrioventricular valve annulus, whether the valve is patent or imperforate. The anatomical presence of an inlet component is unrelated to the patency of its valve. The trabecular component comprises the body of the ventricle distal to the insertion of the papillary muscles. The outlet component supports the arterial valve of the ventricle. It may be a complete muscular structure or may be attenuated to permit continuity between the arterial and atrioventricular valves.[20] In the normal heart the right and left ventricular chambers have characteristic morphology of inlet, apical trabecular,[39] and outlet portions. In hearts with univentricular AV connection the inlet portion of each chamber is abnormal. The outlet portion may also be abnormal or absent. It is the apical trabecular portion of a ventricle that can usually be used to classify a chamber as being of right or left morphology. In the morphologically right ventricle the apical component has characteristic coarse trabeculations. In the normally constituted right ventricle there is also a prominent muscular elevation, the septomarginal trabecula, on the septal surface. This structure may or may not be present when the right ventricle is incomplete. When it is present, a further array of muscle columns within the apical component extends from its anterior edge to the parietal wall of the ventricle. In contrast, the apical component of the morphologically left ventricle has much finer criss-crossing trabeculations and a smooth septal surface.

When two chambers are found within the ventricular mass, one has a right and the other has a left ventricular apical trabecular component. The ventricle receiving the AV valve or valves is usually larger and termed the dominant ventricle. The other ventricle may be described as nondominant, rudimentary, or incomplete. This nondominant ventricle is usually small, but there is considerable variability in its size. We have described this variability as mild, moderate, or severe dominance.[40] Anderson[2] has graded the hypoplasia of the nondominant ventricle in a similar manner, as mild, moderate, or severe. One must also note which components are present in this incomplete ventricle. The apical trabecular component is present and the inlet absent or nearly absent by definition—the presence of the outlet must be specified. The shorthand terms "outlet chamber" and "trabecular pouch" were invented to describe incomplete ventricles without calling them ventricles. These terms describe a nondominant ventricle with and without an outlet component, respectively. Because they are brief and descriptive, their use as verbal shorthand will likely continue.

While the dominant ventricle usually contains all three components, it may lack an outlet component. Hearts have been described with double-inlet left and double-outlet right ventricles.[21]

The relationship of the two ventricles in space is an important variable and must be specified in some manner. In hearts with biventricular AV connection, this has been specified by various authors as d- or l-loop, right- or left-hand ventricular architecture, noninverted or inverted ventricles. In most hearts with univentricular AV connection a similar distinction can be made. In a heart with right-hand morphology it is only possible to place the palmar surface of one's right hand on the septal surface of the right ventricle such that the thumb is in the inlet, the fingers in the outlet and the wrist in the apical trabecular component (Fig. 74–3). In a heart with left-hand morphology only the left hand will fit in this manner in the right ventricle. This method of determining the relative positions of the two ventricles fails when the right ventricle has no inlet component to accept the thumb. Stefanelli et al.[41] suggested using the reverse rule in the left ventricle in this case. However, in some hearts the nondominant ventricle may lie directly anterior or posterior to the dominant ventricle. In such cases, a "long-hand" description of relative positions is required.

When two ventricles are present the communication between them is properly termed a ventricular septal defect. The term outlet foramen was promoted by Anderson for cases in which the second chamber was denied ventricular status and it would have been illogical to call this communication a ventricular septal defect. Outlet foramen is a descriptive term and will probably continue to be used. The term "bulboventricular foramen" is of embryologic origin and its use implies that the communication between the two chambers in the mature heart is a persistence of the bulboventricular foramen in the embryonic heart. The implication is that the nondominant chamber is totally of bulbar origin, while the dominant chamber originates from the primitive ventricle. This term is less appealing since its use requires speculation as to the abnormal embryology.

Rarely, a heart is encountered that has a trabecular pattern typical of neither a right nor a left ventricle and in which, despite axial angiography and microscopic sectioning, no second ventricular chamber can be found. Such ventricles are said to have indeterminate ventricular morphology.

Other hearts have been described in which the ventricular mass contains a trabecular pattern typical of a right ventricle on one side and of a left ventricle on the other, with only a tiny rim of apical ventricular septum. Lev[5] used the term "common ventricle" to describe these hearts. Van Praagh[4] included them in his classification as type C. In the most recent work of Anderson[21] these hearts are considered to have biventricular AV connection with a large ventricular septal defect. They are excluded from the group of hearts with univentricular AV connection. Surgical considerations, however, may be similar to hearts with univentricular AV connection. The correlation between Anderson's terminology and Van Praagh's is given in Table 74–2.

The ventriculoarterial connections must be specified. If two great vessels are present, the connection may be concordant or discordant (normally related or transposed, relative to the ventricular septum), or double outlet from one ventricle may be present. Single outlet may be present with a common arterial trunk, or in cases with aortic or pulmonary atresia. When two great vessels are present it is useful to specify their relative location as well as the ventriculoarterial connection.

ANATOMY

Ventricular Anatomy

Hearts with univentricular AV connection may be subdivided, according to ventricular morphology, into three basic types: hearts with dominant left, dominant right, or indeterminate ventricular morphology. Dominant left or dominant right ventricular morphology can occur with right hand (d-loop) or left hand (l-loop) architecture (Fig. 74–4).

The most common type has a dominant ventricle with an apical trabecular portion of left ventricular type, called double-inlet left ventricle (or, by Van Praagh,[1] single left ventricle). The nondominant ventricle has an apical trabecular portion of right ventricular type. It is usually located anteriorly to the left or right but occasionally is located directly anteriorly. It almost always gives rise to one or both of the great vessels.

Hearts in which the dominant chamber possesses an apical trabecular portion of right ventricular type have been called double-inlet right ventricle (or, by Van Praagh,[1] single right ventricle). The nondominant ventricle has an apical trabecular component of left type and is located posteriorly, usually either more to the left or right. Most commonly, this chamber has neither inlet nor outlet components, though many cases have been documented with outlet of a great vessel from this ventricle. Recognition of hearts with dominant right ventricles often depends on the identification of

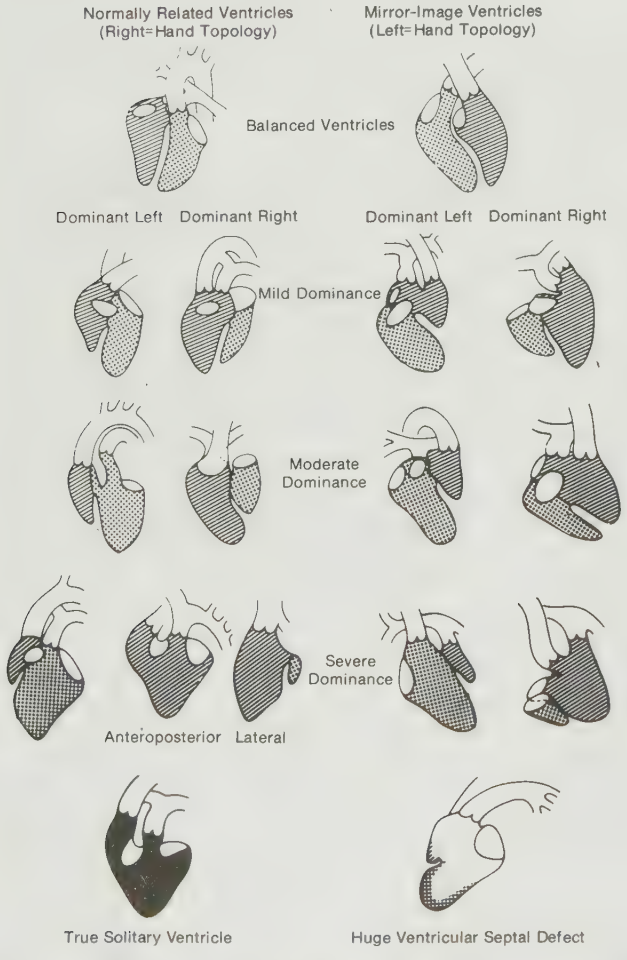

Fig. 74–4. Spectrum of hearts with one large and one small ventricle. Each heart is traced from an actual angiogram. (From Bargeron, L.M.: Angiography of double inlet ventricle. *In* Double Inlet Ventricle. Edited by R.H. Anderson, G. Crupi, and L. Parenzan. Tunbridge Wells, Kent, Castle House Publications, 1987.)

the (usually small) nondominant left ventricles. In vivo this requires high-resolution two-dimensional echocardiography or axial cineangiography. Postmortem identification may require microscopic examination.

Hearts in which only one abnormally trabeculated ventricle can be found are termed hearts with univentricular AV connection and indeterminate ventricular morphology, or by Van Praagh[1] "single ventricle with morphologically undetermined myocardium." Van Praagh expressed doubt that these hearts are different from single right ventricle. Anderson et al.[21] note differences in coronary artery, conduction system, and internal ventricular architecture that support the distinction of these hearts from hearts with dominant right ventricle.

Dominant Left Ventricle

In hearts with a dominant ventricle of left morphology the ventricular septum is displaced anteriorly and does not extend to the crux of the heart. The coronary arteries usually arise from the two aortic sinuses that face the pulmonary trunk. Both right and left coronary arteries give off anterior delimiting branches that provide an external guide to the location of the septum.[5,42] Rarely, a portion of the chordal apparatus of one of the AV valves will insert into the right ventricle. Almost always either the aorta or the pulmonary artery will arise from the right ventricle; rarely, both great vessels or a common arterial trunk will.[43] The communication between the dominant left and nondominant right ventricle is via a ventricular septal defect, occasionally via multiple ventricular septal defects.[44] The ventricular septal defect may or may not be restrictive.[45]

Right-hand Architecture. The Holmes heart is a classic member of this group of hearts. Holmes[46] described this heart in 1824 and his description was republished by Abbott[47] in 1936. There was atrial situs solitus and levocardia with normally related ventricles (right-hand architecture). The AV connection was double inlet to a dominant left ventricle and the ventriculoarterial connection was concordant. The pulmonary artery arose from a rightward chamber with the apical trabecular architecture of a right ventricle. Other hearts with similar morphology have been described.[48] Hearts with a common AV valve, a similar ventricular architecture, and ven-

triculoarterial connection have also been referred to as Holmes hearts.[49]

The ventricular septal defect has a tendency to be restrictive in these hearts. In the setting of right AV valve atresia there is a documented tendency for the ventricular septal defect to become smaller.[50–54] The outlet septum is usually extensive enough to allow resection should enlargement of the ventricular septal defect be required. The chordal apparatus of the right AV valve may insert on the left ventricular surface of the outlet septum and limit resection.[45]

The similarity of the ventricular architecture between the Holmes heart, called by all a "single ventricle," and the ventricular architecture of hearts with classic tricuspid atresia was pointed out by Deanfield et al.[7] There followed a controversy in the literature as to whether classic tricuspid atresia should be considered a single ventricle. Van Praagh et al.[16] and Bharati and Lev[55] argued against. In classic tricuspid atresia, they contended, there were two ventricles, while in the Holmes heart there was a single ventricle. Van Praagh et al. distinguish three possible subarterial chambers: right ventricle, left ventricle, and infundibulum. They state "the infundibulum (outflow tract) is demarcated from the right ventricle (inflow tract) by a ring of infundibular (bulbar) muscle formed by the parietal band, the septal band, and the moderator band." They use the entity "double-chambered right ventricle" to illustrate the difference between the right ventricular inflow and outflow (infundibulum).

It is not clear how one distinguishes the trabeculations of the infundibulum from those of the sinus. Becker et al.[56] point out that the "infundibulum" in tetralogy of Fallot typically comprises only an outlet. It would seem that there is little justification on the basis of the morphologic method for calling the typical nondominant chamber in a heart with a dominant left ventricle, an infundibulum rather than a right ventricle. Of course, it does logically allow one to call hearts with double inlet to a dominant left ventricle, "single ventricle," since the infundibulum is not considered a ventricle. This seems as contrived as the attempts of Anderson to rename the same structure an "outlet chamber" to avoid calling it a ventricle. Again, the problem is trying to preserve the literal meaning of the term single ventricle for a heart that clearly has two chambers within the ventricular mass.

Anderson et al. initially called both the Holmes heart and classical tricuspid atresia, univentricular hearts,[57] denying ventricular status to the nondominant chamber, which they called an outlet chamber in both lesions. Subsequently, they modified their approach to this group of hearts by focusing on the AV connection. They then called the right-sided chamber in both hearts a ventricle. Neither heart would literally have a single ventricle, but both would be included in the group of hearts with univentricular AV connection.

Hearts similar to the Holmes heart but with ventriculoarterial discordance have been described. The outlet septum in these hearts is said to be short, limiting resection of muscle to enlarge the ventricular septal defect. In study of hearts of this type in the Pittsburgh autopsy collection, the ventricular septal defect was found to be crossed by bars of muscle dividing the ventricular septal defect into several subdefects.[56] These bars might have compromised flow through the defect and it might have been desirable to remove them. However, from gross examination the conduction axis appeared possibly to descend through one of the bars.

Left-hand Architecture. The paradigm of single ventricle is called by Van Praagh "single left ventricle," and by Anderson "double-inlet left ventricle." There is left-handed ventricular architecture (l-loop) and ventriculoarterial discordance. There is usually situs solitus of the atria with entrance of both AV valves into a large ventricle with the apical trabecular pattern of a left ventricle. The trabecular pattern in the inlet portion is coarser than a usual left ventricle, and the fine trabecular pattern is only well expressed at the apex. There is usually, but not always, a prominent ridge of muscle at the site where the inlet septum would be expected. It does not carry the conduction tissue. The tensor apparatus of the two AV valves is usually segregated into right and left sides. The nondominant ventricle with apical trabecular component of right ventricular pattern is located anterosuperiorly and to the left with respect to the dominant left ventricle. The ventricular septum is displaced anterosuperiorly and does not reach the crux of the heart. The apical trabeculations of the nondominant chamber have the appearance of those in the right ventricle. The remnants of the septomarginal trabecula can often be distinguished on the septal surface. The two ventricles are connected by a ventricular septal defect (rarely multiple ventricular septal defects), which may or may not be restrictive. The pulmonary artery typically arises from the dominant left ventricle, often with associated valvar or subvalvar pulmonary stenosis. The aorta usually arises from the right ventricle anteriorly and to the left of the pulmonary artery. The subaortic outlet septum tends to be short.

If there is an overriding or straddling valve, the septum involved is an anterosuperior structure and the valve overrides its posterior part usually on the same side as the nondominant ventricle.[56] When there is a common valve it is important to try to distinguish the relationship of the atrial and ventricular septal structures. In a typical atrioventricular septal defect with left ventricular dominance the two septal structures are said to align, normally meeting at the crux with the conduction system normally positioned. In double-inlet left ventricle with a straddling common AV valve, the two septal structures do not typically meet[58] and the conduction-tissue axis is abnormally positioned (Fig. 74–5).

While dominant left ventricle with left-hand architecture is most commonly associated with ventriculoarterial discordance, concordant connection has been described. Freedom et al.[59] described these hearts as isolated ventricular inversion with double-inlet left ventricle. Van Praagh[1] has also described cases. In the Children's Hospital of Pittsburgh collection, 3 of 33 hearts with double-inlet left ventricle had this anatomy.[56] In two, there was fibrous continuity between aortic and the atrioventricular valves, while in two, muscle separated these structures.

Dominant Right Ventricle

The dominant chamber receiving the AV connection has rather coarse apical trabeculations and septomarginal trabecula on its septal surface.[14] In our experience and that of others,[56] it is almost always possible to find a small nondominant ventricle of left ventricular morphology. Van Praagh[4] and Lev[5] and their colleagues excluded from the category "single ventricle" hearts with a dominant ventricle of right morphology in which a small left ventricle could be found. Subsequently, Van Praagh has included hearts with a small left ventricle in his definition of single ventricle.

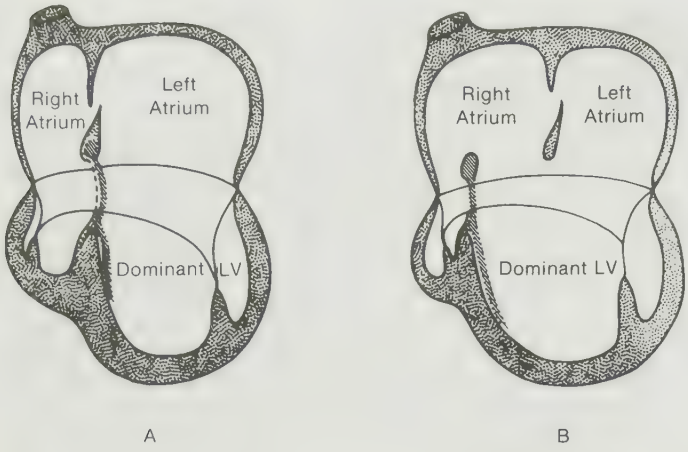

Fig. 74–5. A) Atrioventricular septal defect with left ventricular dominance. B) Double-inlet left ventricle with a straddling common valve. Note the malalignment of atrial and ventricular septal structures. LV = left ventricle; RV = right ventricle. (From Becker, A.E., Anderson, R.H., Penkoske, P.A., and Zuberbuhler, J.R.: Morphology of double inlet ventricle. *In* Double Inlet Ventricle. Edited by R.H. Anderson, G. Crupi, and L. Parenzan. Tunbridge Wells, Kent, Castle House Publications, 1987.)

When a second ventricle can be found, it is almost always posteroinferior to the dominant right ventricle. The ventricular septum extends to the crux and allows application of the right-hand/left-hand rule to distinguish topology. Anterior and posterior descending coronary arteries delimit the position of the posteroinferior nondominant ventricle. In cases with very small chambers these arteries may guide the examiner to the small chamber.[5,14]

From a surgical viewpoint, there is no natural plane of cleavage between the sides of the heart, as is the rule in double-inlet left ventricle. There is no posterior muscular ridge. This makes an operation to divide the dominant right ventricle less attractive.

Right-hand Architecture. Right-hand architecture is by far the most common, with the nondominant left ventricle located posteroinferiorly and leftward. There may be two AV valves, but a common valve is frequently seen. The ventriculoarterial connection is usually double-outlet right, though ventriculoarterial concordance has been reported. Becker[56] reports three common patterns. In the first, there are separate AV valves with the left straddling and double-outlet right ventricle. In the second, a common valve is totally committed to the right ventricle and origin of the aorta is from the nondominant left ventricle. The third exists with right atrial isomerism and is marked by total anomalous pulmonary venous connection and pulmonary atresia. The aorta arises from the dominant right ventricle.

Left-hand Architecture. These hearts are quite rare. There may be two AV valves but usually there is a common valve in the setting of atrial isomerism. The ventriculoarterial connection is usually double-outlet and there may be pulmonary atresia.

Indeterminate Ventricular Morphology

In these hearts the apical trabecular morphology is not typical of either a right or a left ventricle. There is no second ventricle of complementary morphology. One view is that these are hearts of right or left morphology in which the nondominant ventricle has disappeared.[1] Others[56] feel there are anatomic differences that clearly delineate a separate entity. The apical trabeculations are coarser than in the right ventricle and bear no resemblance to a left ventricle. There is no septal surface, either smooth, as typical of a left ventricle or reinforced by the septomarginal trabecula, as in the right ventricle. An abnormal free-standing muscular structure resembling the septomarginal trabecula can sometimes be found in the apical and outlet regions. There often is a posterior ridge of muscle between the two inlet portions that is not typical of double-inlet right ventricle. The coronary arteries can often be used to gain a clue to the location of the nondominant ventricle in hearts with either dominant left or dominant right architecture. In hearts with indeterminate morphology, no prominent descending arteries can be found. There is instead a "wreath" of smaller arteries descending randomly. The conduction tissue is not typical of a heart with a dominant right ventricle.

There is a common association with atrial isomerism, abnormal venous connection, common AV valve, and single outlet with pulmonary atresia. Normal or mirror-image atrial arrangement is also found usually with two AV valves and usually, but not always, with a double outlet from the single ventricle.

Coronary Arteries

The coronary artery distribution is important when an operation requiring ventriculotomy must be performed. The coronary patterns have been described in several reports.[5,7,42,60–62] In the series of Keeton et al.[42] 12 of 17 hearts with double-inlet left ventricle, left-hand architecture and ventriculoarterial discordance displayed a typical pattern. The anterior aortic cusp was the noncoronary cusp. The left coronary artery arose from the left posterior aortic sinus and in 13 of 17 hearts it was the dominant artery. The right coronary artery arose from the right posterior cusp and was the dominant artery in 3 of 17 cases. A major branch, termed a delimiting artery,[63] arose from both right and left coronary arteries. These two delimiting arteries outlined the surface boundaries of the anterior nondominant right ventricle. The right delimiting artery was almost always larger than the left in the postmortem study of Keeton, but in an angiographic study[60] the left was said to be larger. As the main coronary arteries continued in the atrioventricular groove they gave off two to six large branches parallel to the delimiting artery. Variations to the typical anatomy occurred in 5 of the 17 hearts (Fig. 74–6) studied by Keeton.

Keeton examined three hearts with double-inlet left-ventricle, right-hand architecture with ventriculoarterial discordance. Two had typical delimiting arteries. In the other, the right coronary arose from the left anterior cusp and crossed the front of the heart with no delimiting arteries. A single heart with double-inlet left-ventricle, right-hand architecture and ventriculoarterial concordance (Holmes heart) was found to have normal origin of the coronary arteries with typical delimiting arteries. In contrast to the hearts previously mentioned, the right anterior surface of the ventricle was relatively free of vessels. This is important since a number of the hearts undergoing a ventriculotomy for a septation operation suffered transection of possibly important coronary branches.

Deanfield et al.[7] examined the coronary anatomy in postmortem specimens with double-inlet left ventricle, with classic tricuspid atresia, and with pulmonary atresia intact septum. Of the hearts with pulmonary atresia intact ventricular septum, 93% had the posterior extent of the ventricular septum delimited by a coronary

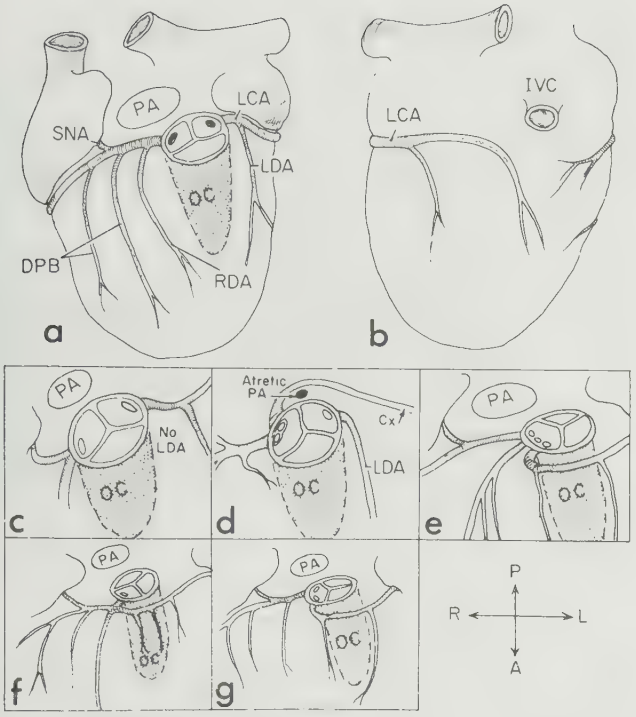

Fig. 74–6. Variations in coronary artery anatomy seen with dominant-left-ventricle and left-hand architecture: a) anterior view; b) posterior view of typical pattern; c) through (g) atypical patterns. SNA = sinus nodal artery; PA = pulmonary artery; LCA = left coronary artery; OC = outlet chamber; LDA = left delimiting artery; DPB = delimiting parallel branch; RDA = right delimiting artery; IVC = inferior vena cava; Cx = circumflex artery; R = right; P = posterior; A = anterior; L = left. (From Keeton, B.R., et al.: Anatomy of coronary arteries in univentricular hearts and its surgical implications. Am. J. Cardiol., *43*:569–580, 1979.)

artery descending at the crux. In contrast, in the hearts with double inlet, and those with tricuspid atresia, the posterior extent of the septum was marked by a delimiting artery descending at the acute margin rather than at the crux. Additional parallel arteries between the delimiting artery and the crux were also seen in most of these specimens.

Conduction System

The anatomy of the specialized conduction system is of great surgical importance in hearts with univentricular AV connection. Observations would suggest that the formation of a normal AV conduction system requires the development of the inlet portion of the ventricular septum to bring the sheet of conduction tissue astride the trabecular portion of the developing septum, into contact with the atrial conduction tissue at the level of the central fibrous body. If this process fails to occur, an abnormal conduction system will develop. The ring of specialized tissue associated with the atrioventricular valve ring is capable of forming a node (or nodes) in association with a penetrating bundle at sites other than the site of the normal AV node. Usually the abnormal node is formed in the anterior or anterolateral portion of the right atrial portion of the AV valve ring. The relation of the two ventricles has a great effect on the location of the contact between the ventricular septum and the conduction tissue associated with the AV valve ring. Hearts with similar ventricular relation in general have similar AV conduction systems. The mode of atrioventricular connection does affect the location of the AV node, particularly in the hearts with absence of one AV valve. The atrial situs also affects the sidedness of the sinoatrial and AV nodes in normally related and inverted atrial relations. When the atrial relations are ambiguous,[64] the sinoatrial node is abnormal—dual with bilateral right-sidedness, hypoplastic with bilateral left-sidedness. In either case, there may be dual AV nodes connected by a sling of specialized conduction tissue.

The description of the conduction system in the various hearts will be organized according to ventricular relationships and subgrouped by mode of AV connection. Normal atrial situs may be assumed unless specifically stated otherwise.

Right-hand Architecture

Dominant Left Ventricle. When the ventricles are normally related and there is left ventricular dominance, the nondominant right ventricle is located anteriorly and to the right. The ventricular septum does not extend to the crux of the heart but meets the AV valve ring more rightward and anteriorly than usual. When there is double inlet (as in the Holmes heart), the inlet portion of the ventricular septum is absent and it is the trabecular portion of the ventricular septum that makes contact with the conduction tissue of the AV ring. This leads to the development of an anterior node with a nonbranching bundle that runs along the left ventricular side of the trabecular septum. If approached from an incision on the left side of the left ventricle, the bundle would be seen beneath the ventricular septal defect (Fig. 74–7). If approached from the right ventricle, the bundle would be on the left ventricular aspect rightward, anatomically, and beneath the ventricular septal defect.

When the right AV connection is absent (classic tricuspid atresia) the disposition of the conduction tissue within the ventricles is similar. The position of the AV node was initially reported to be normal.[65] Other observers[66] found the AV node posterolateral to the dimple in the floor of the right atrium; however, in most cases, there was anterior extension of the nodal tissue and in most of these the penetrating bundle took origin from the anterior extension. The bundle was found on the right parietal wall of the main ventricular chamber and was buried in the myocardium, rather than lying on the crest of the septum as it does in a normal heart.

The form and location of the AV nodal tissue is explained by the fact that regular and anterior nodes can only exist in isolation when the right orifice is formed. When the orifice of the right valve is absent, the junction of the trabecular septum moves more toward the crux and the anterior node becomes merged with the regular node (Fig. 74–8).

Absence of the left AV valve usually is associated with left-hand ventricular architecture, and in this situation there is an anterior AV node. When the ventricles are normally related, one would expect an anterior node with a disposition of the ventricular conduction system similar to double inlet as described above.

When straddling occurs, the most likely location of the connecting AV node will be somewhere along the right atrial orifice close to the point of contact between the anterior or posterior limb of the trabecular septum with the AV orifice; with a straddling right AV valve this would be expected to be posterolateral.[67] There

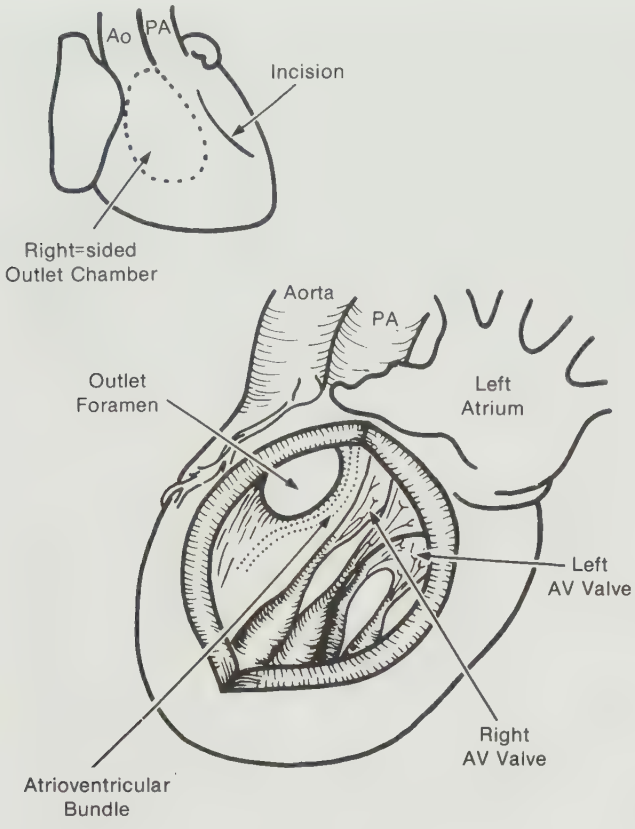

Fig. 74–7. Conduction axis in dominant left ventricle with right-hand architecture, seen from an incision in the dominant left ventricle. Ao = aorta; PA = pulmonary artery; AV = atrioventricular. (From Becker, A.E., Wilkinson, J.L., and Anderson, R.H.: Atrioventricular conduction tissues: A guide in understanding the morphogenesis of the univentricular heart. *In* Etiology and Morphogenesis of Congenital Heart Disease. Edited by R. Van Praagh and A. Takao. Mount Kisco, NY, Futura, 1980.)

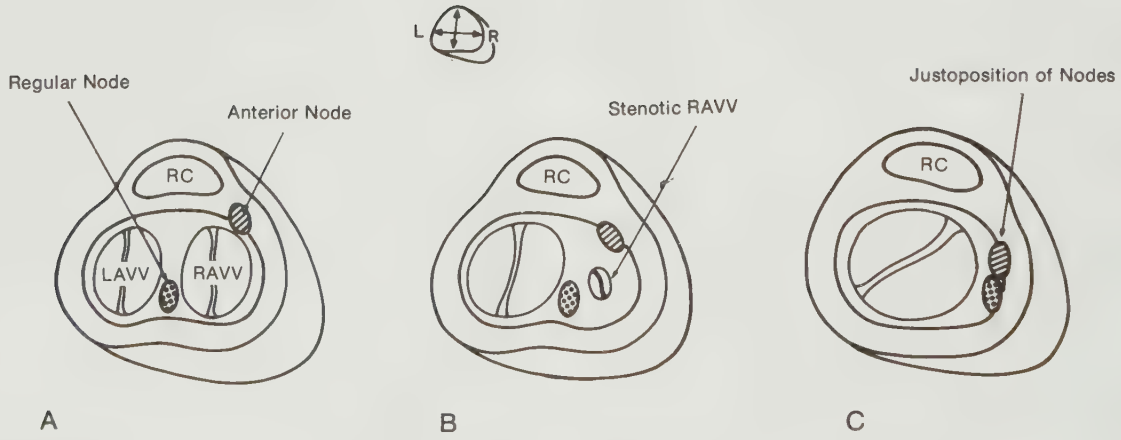

Fig. 74–8. Diagram illustrating how anterior and posterior nodes can only exist as discrete structures when there is a right atrioventricular orifice. With absent connection these two nodes are placed into juxtaposition. A) Double-inlet ventricle; B) double-inlet ventricle, stenotic right atrioventricular valve; and C) absent right atrioventricular connection. L = left; A = anterior; P = posterior; R = right; RC = rudimentary chamber; LAVV = left atrioventricular valve; RAVV = right atrioventricular valve. (From Becker, A.E., Wilkinson, J.L., and Anderson, R.H.: Atrioventricular conduction tissues: A guide in understanding the morphogenesis of the univentricular heart. *In* Etiology and Morphogenesis of Congenital Heart Disease. Edited by R. Van Praagh and A. Takao. Mount Kisco, NY, Futura, 1980.)

is a spectrum of straddling. As the valve becomes more committed to the right ventricle, the posterior extent of the trabecular septum and thus the location of the abnormal node moves more posteriorly toward the crux.[68]

Dominant Right Ventricle. In these hearts the nondominant left ventricle is posterior and to the left. The ventricular septum is presumably mostly trabecular. However, this septum does run to the crux of the heart and may have a component in that area that is similar in embryonic origin to the normal inlet septum. The AV node has been described to be in its normal position with respect to the atrial landmarks.[69] The penetrating bundle usually passes directly onto the septum, though in one case it ran onto a trabecula on the posterior wall.

A case of absent left AV connection with a microscopic left ventricle has been reported.[68] The conduction system was as with double inlet described above. The tiny left ventricle was actually found by following the conduction system on microscopic sections. Presumably, the conduction system with absent left AV connection would be similar to that in double inlet. Straddling would not be expected to alter the conduction system.

Left-hand Architecture

Dominant Left Ventricle. When there is left-hand architecture and a dominant left ventricle, the nondominant right is located anteriorly and to the left. The ventricular septum does not extend to the crux, but is displaced anteriorly and to the left. When there is double inlet, the regular AV node is hypoplastic and does not make contact with the ventricular myocardium. The atrioventricular node and penetrating bundle are anterior and right-sided.[70–72] The penetrating bundle runs an extensive course across the anterior aspect of the outflow tract of the left ventricle then down the right margin of the ventricular septal defect. Bharati and Lev[71] reported two cases in which the entire right atrial roof was formed of node-like tissue, and in one of these the anterior node was divided into two parts. One part gave off the penetrating bundle while the other gave off Mahaim fibers to the ventricular myocardium.

Should the surgeon desire to enlarge the ventricular septal defect, he would resect the margin perceived as inferior when viewed through the right atrium (Fig. 74–9). A previous recommendation that the roof of the defect be resected[73] has been retracted.

It should be pointed out that this discussion assumes a usual ventricular septal defect between outlet and trabecular portions of the ventricular septum. If, as has been reported,[26,74] there is an additional defect in the apical trabecular septum, the conduction tissue could pass through the bar of muscle separating the two defects. If the usual defect undergoes spontaneous closure, the bundle may run through the roof of the remaining ventricular septal defect.

When this ventricular pattern is associated with absence of the right AV connection[68] the AV node is as described for classic tricuspid atresia as above. The intraventricular portion is as described immediately above for double inlet with an extensive course of the nonbranching bundle.

When the left AV valve is absent, the right AV valve provides a separation of the regular and anterior nodes. The regular node makes no contact with the anteriorly displaced septum, therefore the anterolateral node gives rise to the penetrating bundle, which takes the same extensive intraventricular course described for double inlet.

When there is straddling of the left AV valve in this ventricular arrangement, the node and conduction tissues are similar to double inlet described above, regardless of the degree of straddling.[68] To my knowledge, the conduction system in straddling right valve has not been described.

Dominant Right Ventricle. In this arrangement the nondominant left ventricle is located to the right. The posterior extent of the ventricular septum reaches the crux. Since the ventricular architecture is left-hand, one might expect an anterior AV node. On the other hand, the septum does reach the crux, and when this occurs in double-inlet right ventricle with normally related ventricles, the AV node is in regular position. The conduction tissue in a single heart with this morphology has been described.[75] In this heart both anterior and regular AV nodes were found placed close together and connected by a "sling" of conduction tissue passing through the fibrous annulus but not related to the trabecular septum. The nonbranching bundle descended to a free running trabecula in the right ventricle, the trabecular septal tissue itself being devoid of conduction tissue. The trabecula was felt to represent the septomarginal trabecula of the normal right ventricle.

The anatomy of the conduction tissue in hearts with left-hand architecture and biventricular AV connection with straddling right AV valve has been described. In these hearts both regular and anterior nodes were present, connected by a "sling" of conduction tissue.

Two hearts with left-hand architecture, dominant right ventricle and absent right AV connection and straddling left AV valve have been described.[68] A node was present in the floor of the blindly ending right atrium, from which an anterior bundle penetrated and ran onto the anterior margin of the septal defect. From there, a sling of conduction tissue ran along the septal crest, ascending to penetrate the annulus and form a second node in the posterior wall of the left atrium. Absence of the left AV connection has not been reported with this ventricular architecture.

Indeterminate Ventricular Morphology

In hearts in this group there is a second ventricle present and therefore no apical septal structure. These hearts would be expected to have an anterior node and the bundle should simply run down the parietal wall of the ventricle at the acute margin of the AV junction.[76] The presence of a prominent septomarginal trabecula has been seen to modify this arrangement.[77] In one heart this trabecula that carried the bundle extended to the underside of the atrium. The node was in the atrial septum and the bundle penetrated at the apex of the triangle of Koch. In another case the trabecula ran to the underside of the ventriculoinfundibular fold.

In hearts with biventricular AV connection and a large ventricular septal defect, the AV node is usually normally placed and the bundle runs in a remnant of inlet septum on the posterior wall of the ventricular mass[78,79] Becker et al.[56] reported a case in which the posterior ridge became diminutive as it approached the crux. One anterior prominent marginal trabeculation was found to carry the bundle from an anomalous anterolateral node.

General rules for prediction of location of conduction tissue are presented in Table 74–3.

EMBRYOLOGY

The embryology of the normal heart is incompletely understood. Numerous terminologies have been used to describe the various

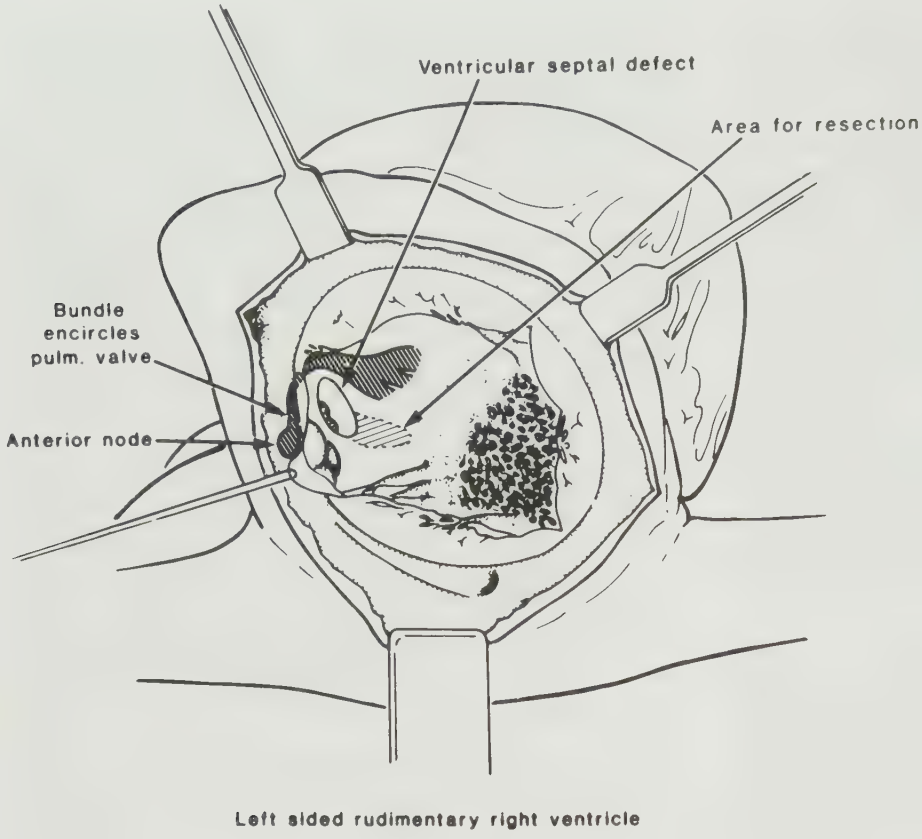

Fig. 74–9. View of the conduction axis and area of safe resection to enlarge the ventricular septal defect in dominant left ventricle with left-hand architecture, seen through right atriotomy and right atrioventricular valve. (From Anderson, R.H., et al.: Disposition of the conduction tissues. *In* Double Inlet Ventricle. Edited by R.H. Anderson, G. Crupi, and L. Parenzan. Tunbridge Wells, Kent, Castle House Publications, 1987.)

Table 74–3. Rules for the Prediction of Conduction Tissue

Is there a septum in the ventricular mass?
No —solitary indeterminate ventricle
There will be an anterolateral node (unless trabeculation joins atrial septum)
Yes
Does the septum extend to the crux?
No —double-inlet left ventricle
There will be an anterolateral node
Yes—but deviated to produce double-inlet right-ventricle conduction tissue determined by ventricular topology
Right-hand pattern—node in triangle of Koch
Left-hand pattern —anterior node or sling
Yes—but hypoplastic apical structure, huge ventricular septal defect
Inlet septal remnant—node in triangle of Koch
No inlet septum —anterior node
Left-hand topology —anticipate anterior node

From Anderson, R.H., et al.: Disposition of the conduction tissues. *In* Double Inlet Ventricle. Edited by R.H. Anderson, G. Crupi, and L. Parenzan. Tunbridge Wells, Kent, Castle House Publications, 1987.

structures and structural changes. Until direct observation of the development of normal and abnormal human hearts is possible, comments about the development processes will remain somewhat speculative.

The ventricular mass is first considered. The right- or left-handedness of the ventricular pattern has been presumed to be a consequence of the direction of the acute bend in the heart during looping. If the convex margin is directed to the right (d-loop) the right-handed pattern will result, if to the left (l-loop) the left-handed pattern. Even this generally accepted speculation has been doubted.[80]

Dominant Left Ventricle

The hearts with double inlet via a common valve to a dominant left ventricle resemble the embryonic heart[81,82] at Streeter's stage XIII.[83–85] At this stage, the partially divided atrial mass communicates via an undivided AV valve with the descending limb of the bulboventricular loop variously called the primitive ventricle,[5,86] left ventricle,[81] inlet segment,[87] or proampulla.[88,89] There is controversy as to the embryonic derivation of the left and right ventricles in the normal heart. De la Cruz and Miller,[81] based on Streeter, state that the primitive ventricle (descending limb) gives rise to the sinus of the definitive left ventricle only and that the bulbus cordis gives rise to the sinus of the right ventricle and to the outflow portions of both right and left ventricles.

Lev[5] quotes Pernkopf and Wirtinger[88] in stating that the descending limb, or proampulla, gives rise to the sinuses of both right and left ventricles while the ascending limb, metampulla or bulbus, gives rise to part of the sinus of the right ventricle and to

the outlet portion, conus, of both ventricles. The work of Wenink[87] seems to support the latter opinion. Van Praagh et al. reexamined the work of Pernkopf and Wirtinger and concluded that the difference is a misinterpretation of terms, i.e., this work in fact agrees with Streeter's concerning the derivation of the ventricles. If De la Cruz and Miller are correct, then the dominant ventricle is the primitive left ventricle and the nondominant chamber is the right ventricle. If Pernkopf and Wirtinger (as interpreted by Lev) are correct, then the dominant ventricle is not simply the primitive left ventricle but also contains a portion of the right sinus.

The nature of the structure separating the dominant and nondominant chambers of these hearts has been debated. De la Cruz and Miller suggested that it is the malaligned posterior septum, assuming an anterior position as a consequence of failure of migration of the right atrioventricular canal to the bulbus. They quote as evidence in support of this concept the fact that in some cases the right valve straddles the anterior septum. These hearts with straddling are thought to represent intermediate steps in the migration of the right AV orifice from left ventricle to the bulbus.

Anderson et al.[86] examined several pathologic specimens with double-chamber right ventricle in which both anterior and posterior septa were felt to be present and concluded that one could not possibly be formed by realignment of the other. Based on these hearts they concluded that the anterior septum is a persistent right bulboventricular ridge.

Van Praagh et al.[1] concluded that it is the displaced ventricular septum that separates the two chambers. They speculated that, when the right ventricle fails to evaginate or outpouch from the metampulla, then expansive growth fails to carry the ventricular septum leftward to underlie the atrial septum and separate the developing AV valves.

Van Mierop[90] believes that the structure separating the two chambers is homologous with the major part of the normal ventricular septum and that it is displaced to the right. This, he says, occurs when the AV canal is abnormally oriented, becoming "trapped" to the left of the bulboventricular septum. With further expansion of the right AV ostium, the septum is pushed rightward and blends with the trabecula septomarginalis, while the posterior medial muscle bundle[5] cannot blend with the posterior portion of the muscular septum. This posterior ridge formed concomitant with partitioning of the AV canal does retain its normal relationship with the atrial septum, crux cordis, and the posterior descending artery.

Dominant Right Ventricle

Munoz-Castellanos et al.[91] described two cases of double inlet to a dominant right ventricle. The two ventricles communicated via a basilar ventricular septal defect, and there was straddling and overriding of the AV valve. They recognized this defect to be much more rare than double-inlet left ventricle. This, they supposed, was because double-inlet left ventricle represented the persistence of a normal developmental stage while double inlet right ventricle represented an alteration in normal development of the AV connections. They postulated that double-inlet right ventricle originates from a precocious and prolonged widening of the AV canal from left to right. This process, beginning at Streeter's Horizon XIII and normally continuing through Horizon XV, does not stop at the time when the interatrial septal complex is aligned with the interventricular septum, but is continued exaggeratedly to the right.[92] The usual underdevelopment of the left ventricle in these hearts is presumed secondary to the altered hemodynamics resulting from the displacement of the AV canal. Other authors[87,93,94] deny the rightward shift of the AV canal as a process in normal development. Dor and Corone[93] would say the ventricular septum shifts to the left. Wenink[87] contends the normal septation of the inlet segment results in the right portion of the AV canal being related to the right portion of the inlet segment of the ventricular mass from the earliest appearance of the inlet septum. Using this concept one might postulate that double-inlet right ventricle results from an abnormal partition of the inlet segment together with failure of the left portion of the inlet segment to enlarge.

The mode of atrioventricular connection seems determined by events taking place in the septation of the AV canal. If the endocardial cushions develop normally, then the canal will be divided, resulting in double inlet. A later abnormality may result in one of these orifices being imperforate. If the partitioning fails to occur, a common AV valve results. If partitioning occurs asymmetrically, stenosis of one orifice will result. Absence of an atrioventricular connection is postulated to occur when the endocardial cushions develop at the periphery of the atrioventricular orifice. The atrial septal structures then align with the cushions (Fig. 74–10).

The presence of overriding is a consequence of a malalignment between the structures dividing the atria/atrioventricular canal and the developing ventricular septum. The tensor apparatus develops much later as a result of undermining of the ventricular myocardium.[87] This later process of ventricular undermining then is responsible for the varying degrees of straddling.

INCIDENCE

Since this chapter deals with a group of hearts and not a single anatomic diagnosis, and since many different names have been used it is difficult to state the incidence precisely. Kidd[95] has reported finding a single ventricle in 1.1% of children with congenital heart defects. Thies et al.[40] reported 218 local cases accumulated over a 20-year period at University of Alabama Birmingham. Macartney et al.[62] found 42 cases in a 5-year period. While most patients have no chromosomal abnormality, case reports[96] documented occasional associations. Occurrence in siblings has been reported.[43]

The relative incidence of the different ventricular morphologies within this group of hearts is also difficult to obtain. Hearts with a dominant right ventricle have only recently been recognized and identified as a part of this group. In the series of Van Praagh et al.[4] hearts with double inlet to a right ventricular chamber were only included if a second small chamber was not present. However, some may have had tiny left ventricles, since microscopic sectioning is sometimes required to identify these chambers. This series of 60 hearts contained 47 (78%) with a dominant left ventricle, which Van Praagh et al. called type A; only 3 hearts (5%) with dominant right ventricle, which they called type B; 6 hearts (10%) with a single chamber of indeterminate morphology, which they called type D; and 4 hearts (7%) with absent or rudimentary development of the sinus portion of the ventricular septum, which they called type C.

In a second series Van Praagh et al.[1] reported an additional 31

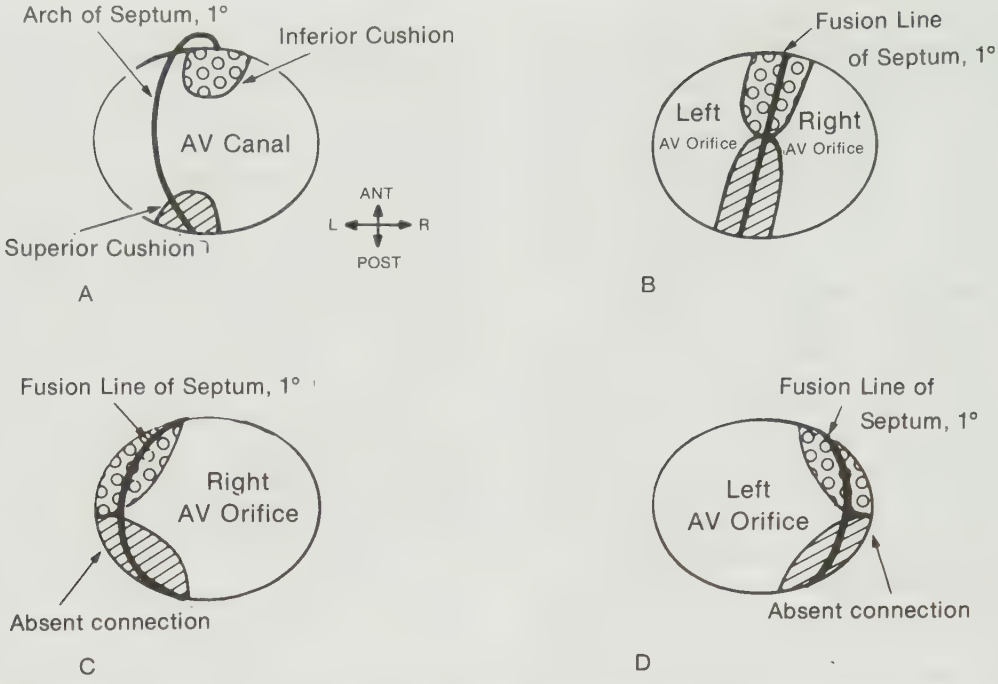

Fig. 74–10. Proposed mechanism of producing A) normal and abnormal development, B) double inlet, C) absent left atrioventricular connection, or D) absent right atrioventricular connection. (From Becker, A.E., Wilkinson, J.L., and Anderson, R.H.: Atrioventricular conduction tissues: A guide in understanding the morphogenesis of the univentricular heart. *In* Etiology and Morphogenesis of Congenital Heart Disease. Edited by R. Van Praagh and A. Takao. Mount Kisco, NY, Futura, 1980.

cases, of which 23 (74%) had dominant left ventricle—14 (45%) with l-loop and 9 (29%) with d-loop. Of the 8 (26%) cases with dominant right ventricle (they allowed a tiny left in this series), 6 (20%) had d-loop and 2 (6%) had l-loop.

In an angiographic study,[44] in which hearts with absence of one AV connection were included, 36 of 54 patients had dominant left ventricle and 13 dominant right while 5 were felt to have indeterminate morphology. Of the hearts with dominant-left architecture, the nondominant right was anterior and rightward in 17, leftward in 12 and directly anterior in 6. Of the 13 patients with a dominant right ventricle, a second ventricle of left ventricular type could be seen posteriorly in 8, though it is not mentioned how many were right- or left-sided.

The most detailed information on pathologic specimens is reported by Anderson et al.[97] This series of hearts was obtained from several institutions and included hearts with one absent AV connection as well as hearts with double inlet. Of 237 hearts, 140 had dominant left ventricle, 34 dominant right ventricle, and 41 indeterminate morphology. Of these hearts, 87 had a dominant left ventricle and absent right AV connection, and thus would be listed in other series as classic tricuspid atresia. While the right- or left-handedness of the ventricular mass is not listed specifically, this can be inferred from the position of the nondominant chamber (Table 74–4). The details concerning atrial situs (Table 74–5), nature of the nondominant ventricle (Table 74–6), mode of atrioventricular connection (Table 74–7), and arterial connections (Table 74–8) are listed.

Of interest, approximately one quarter of the hearts with a second chamber in the ventricular mass exhibited straddling of one of the atrioventricular valves or of part of a common valve. In the majority the straddling was said to be minimal while in some hearts it approached 50%. In a surgical series Stefanelli et al.[41] reported an incidence of straddling of 13%.

The detailed information from the surgical series at University

of Alabama Birmingham includes cases with AV valve atresia. The information is listed by the type of ventricular architecture and dominant ventricle. (Tables 74–9, 74–10, and 74–11). Associated cardiac lesions, common in all series, are detailed in Table 74–12. Coarctatation and interruption are not listed in this table. In a series of patients presenting in the first year of life, these lesions were found in 16%. Other associated anomalies found in this series are listed in Table 74–13.

The incidence of dextrocardia is not given in the series of Anderson et al.,[97] but in Van Praagh and colleagues' series[4] 11 of 60 hearts exhibited dextrocardia, 7 with dominant left ventricle (type A), 2 with indeterminate ventricle (type D), and 2 with large ventricular septal defect and biventricular connection (type C). In a series of hearts with dextrocardia[98] 10 of the 16 hearts with situs solitus, 2 of the 11 with situs inversus, and 2 of the 6 with situs ambiguus were said to have univentricular hearts.

Of the 43 cases reviewed by Lev et al.,[5] 7 had dextrocardia. Abnormalities of atrial situs associated with abnormalities of systemic and pulmonary venous connections, multiple or absent spleens and common AV valves are more commonly seen with dominant right ventricle, and ventricles of indeterminate morphology, though cases with dominant left ventricle are seen.[97,99]

CLINICAL FINDINGS

Most patients present early in life with cyanosis due to inadequate pulmonary blood flow, or congestive heart failure if pulmonary artery blood flow is unobstructed or if pulmonary venous return is obstructed. A few children who are congenitally optimally palliated will present later in childhood with asymptomatic murmur and mild clinical cyanosis.[100] Decreasing exercise tolerance or increasing cyanosis may bring them to the attention of a cardiologist.[101] A few neonates with left outflow obstruction will have onset of poor perfusion when the ductus closes in the first few days of life. Aortic atresia, through rare, has been described.[1] From a series of all patients with single ventricle treated surgically,[41] 25% of the patients came to their first operation by 3 months of age, 50% by 22 months of age, and 75% by 7 years of age.

Pulmonary stenosis was present in 64% and atresia in 5% of the cases reported by Stefanelli et al.[41] When present, this usually determines the clinical presentation. Patients with pulmonary atresia or severe pulmonary stenosis may present with profound cyanosis and acidosis when the ductus spontaneously closes in the first few days of life. In earlier series, these patients probably died without coming to surgery. More recently, the widespread availability of prostaglandin E_1, used to reopen the ductus, has allowed more of these patients to survive to operation. In addition, the patients coming to operation now are usually not acidotic or severely cyanotic.

If the pulmonary blood flow is restricted by pulmonary stenosis but adequate to maintain adequate systemic oxygenation, then no palliative procedure is required. Pulmonary blood flow may become inadequate with growth as the fixed pulmonary valvular ostial size fails to grow at the same pace as the rest of the patient. Obstruction to pulmonary blood flow may also be subvalvar, caused by a restrictive ventricular septal defect or hypertrophy of subpulmonary muscle. Either of these types of subpulmonary stenosis may exhibit progressive obstruction and complete occlusion of the pulmonary outflow.[52] Much less commonly, subpulmonic obstruction may be due to redundant fibrous tissue arising in association with one of the AV valves.

It should be pointed out that while the degree of cyanosis is usually determined by the amount of pulmonary blood flow, in patients with intact atrial septum and significant streaming of flow within the ventricles cyanosis may be less (favorable streaming) or greater (unfavorable streaming) than expected if full mixing were taking place.[102]

Patients without pulmonary stenosis may present with a murmur or gallop in the first few days of life, but clinical symptoms do not usually become apparent until three to six weeks of age, when the fall in pulmonary vascular resistance allows excessive pulmonary blood flow. The findings at that time will be congestive heart failure with tachypnea, subcostal retraction, poor feeding, hepatamegaly, and splenomegaly. Digitalis and diuretics allow shortterm improvement but palliative or two-stage "corrective" surgery[103] is required for longterm survival.

In patients with left AV valve atresia or severe stenosis and nearly intact interatrial septum, symptoms of pulmonary venous hypertension may develop as arteriolar resistance falls and pulmonary blood flow increases. This problem may also become apparent following placement of a systemic-to-pulmonary-artery shunt. Ideally, the restriction to pulmonary venous return should be recognized by echocardiography and aggressively treated by balloon atrial septostomy in the neonatal period. If recognized later, balloon atrial septostomy is less likely to be successful and either blade septostomy or Blalock–Hanlon atrial septectomy will be required. It should be pointed out that obstructed total anomalous pulmonary venous connection occurs, though rarely, with a single ventricle and that symptoms in this form of obstruction may also be provoked by a successful shunting procedure.[104]

Rarely, a patient with severe AV valve insufficiency (usually of a common AV valve) may present with severe intractable heart failure. Though valve replacement has been accomplished in older patients, the outlook for a neonate with severe AV valve insufficiency is grim.

Subaortic obstruction may appear in the first few days of life.[4] If present, the fetal circulation pattern has usually been abnormal

and there is often a reduction in the size of the ascending aorta and severe coarctation or interruption of the aortic arch. Such patients depend on the patent ductus arteriosus for systemic blood flow. When the ductus undergoes spontaneous (or unfortunate surgical or indomethacin closure) in a child with unrecognized heart disease inadequate perfusion leads to profound acidosis and death. Administration of prostaglandin E_1 may reopen the ductus if spontaneously closed. The long-term surgical outlook for such patients is grim (see section on palliative surgery).

DIAGNOSIS

The physical findings will depend more on the physiology than on the particular ventricular morphology or mode of atrioventricular connection. With pulmonary stenosis or atresia, cyanosis will be more remarkable. With stenosis there will be a harsh ejection murmur at the base of the heart. If subpulmonary stenosis progresses, the murmur may become quieter and shorter and cyanosis may deepen. If there is obstruction to pulmonary venous return, the ejection murmur of pulmonic stenosis may be minimized. With pulmonary atresia there will be no harsh ejection murmur, but a continuous murmur from ductal patency may be heard. The second heart sound will be single. If the aorta is anterior, the second heart sound may be loud and the component due to the pulmonary valve, if present, may be difficult to appreciate.

If there is no pulmonary stenosis and a nonrestrictive ventricular septal defect, there will usually be a nonspecific systolic murmur

Table 74–10. Ventricular Architectural Pattern and Dominance and the Nature of the Univentricular AV Connection in Surgical Cases of Univentricular AV Connection (UAB; 1967–July 1982)

Ventricular Architectural Pattern	*Main (Dominant) Ventricular Chamber*	*Number of Cases*	*AV Valves*			
			Common	*Double Inlet*	*Left-Sided AV Valve Atresia*	*Right-Sided AV Valve Atresia*
Solitary ventricle	NA	23 (20%)	13	10	0	0
Two ventricles						
Right-handed (d-loop)		37 + 89	6	24	6	1 + 89

Deanfield, J.E., et al.: Factors influencing presentation and prognosis. *In* Double Inlet Ventricle. Edited by R.H. Anderson, G. Crupi, and L. Parenzan. Tunbridge Wells, Kent, Castle House Publications, 1987.

and a diastolic flow rumble or gallop. If there is a subaortic stenosis,[105] there will usually be a harsh murmur, but there may be important narrowing of the ventricular septal defect without a loud murmur. If there is associated coarctation and the ductus has closed, there will be decreased femoral pulses. If the ductus is still patent, there may be brisk lower-extremity pulses even in the presence of severe coarctation or interruption.

CHEST ROENTGENOGRAPHY

The findings on chest roentgenography are dependent on the degree of pulmonary outflow obstruction. With moderately restricted pulmonary blood flow there will generally be a near-normal heart size and pulmonary vascular markings. When pulmonary blood flow is severely obstructed, the pulmonary vascular markings will be decreased. When there is mild or no pulmonary stenosis, there will be cardiomegaly with increased pulmonary vascular markings. The sidedness of the stomach bubble may provide information about the abdominal situs. If atrial isomerism is suspected, high kilovolt films or tomograms[106] may allow evaluation of bronchial anatomy. If pulmonary venous return is severely obstructed in the setting of total anomalous pulmonary venous return or mitral atresia/stenosis, the lung fields will assume a reticular pattern and the heart size will be normal to mildly increased. In patients with dominant left ventricle and left-hand architecture a notch can sometimes be seen on the left heart border marking the site of the small right ventricle. In these patients the left heart border will often have a straight appearance, as seen in patients with congenitally corrected transposition.

ELECTROCARDIOGRAPHIC FINDINGS

The electrocardiographic findings are quite variable.[107,108] There is generally sinus rhythm and the PR interval is generally normal, though first-degree heart block was present in 30% of the patients reported by Gillette.[109] None of the patients with first-degree heart block progressed to complete heart block during followup. Seven patients had serious supraventricular tachydysrhythmias including atrial flutter in three. Four patients had Wolff–Parkinson–White syndrome and one Lown-Ganong–Levine syndrome. Congenital complete heart block will be present in a few patients: 3 of 116 surgical patients[41] and 5 of 105 patients reported by Gillette.[109] Heart block did not develop in any patient followed without surgery by Moodie et al.[101] Supraventricular tachycardia was documented in three of their patients and in both the surgically palliated[110] and nonpalliated series, dysrhythmia was listed as a cause of death. Sudden death was seen in these patients and in patients who underwent a septation procedure.[41,111]

Efforts to relate the vectorcardiogram or the sidedness of hypertrophy on scalar electrocardiography with the morphologic type of the ventricular mass have been disappointing.[107,108] A number of patients will have no evidence of ventricular hypertrophy. The frontal plane QRS axis will often be normal but may be found in the upper quadrants. The P-wave axis may be abnormal, especially when atrial isomerism and bilateral left-sidedness are present.

Electrophysiologic testing has been reported both in the catheterization laboratory[109,112] and in the operating room.[79,113] The intraoperative studies confirmed expected sites of specialized conduction tissue. The sites of first degree AV block were found to be variable and multiple sites of atrioventricular delay could be found in individual patients.

TWO-DIMENSIONAL AND DOPPLER ECHOCARDIOGRAPHY

M-mode echocardiography is capable of demonstrating the presence of one large chamber within the ventricular mass. Usually the number and location of AV valves can also be discerned.[114] The annulus size and general relative location of the semilunar valves can be worked out by an experienced M-mode operator.[115–120]

Two-dimensional echocardiography greatly reduced the time required to obtain this information and provided much more secure information about spatial relationships.[121–123] Clues to the situs are obtained from the systemic venous anatomy.[124] The type and mode of AV connection are well seen.[125] Straddling and overriding of AV valves may be assessed more accurately by echocardiography than by angiography.[58] The presence and size of atrial septal defects can be evaluated. When an outlet chamber is present, the chamber and the size and location of the ventricular septal defect can usually be seen.[126] The small posterior left ventricle associated with a dominant right ventricle may be seen, or it may be too small to be seen. The differentiation of the morphologic type of the main ventricle may often be inferred from the associated nondominant chamber, but the apical trabecular pattern of the ventricles is not reliably discernible with current techniques.[123,127]

The ventriculoarterial connections and spatial relationships can usually be well seen, as can the presence of subvalvar or valvar stenosis. This usually requires both parasternal long- and short-axis views. From the suprasternal notch the sidedness of the arch and location of the patent ductus, if present, can be visualized. In cross section one can usually visualize the bifurcation of the pulmonary arteries. The systemic venous return can also be seen from this view, often showing bilateral superior caval veins. Deep in relation to the pulmonary arteries, the pulmonary veins can usually be seen entering the left atrium or forming a confluence behind the left atrium. In the presence of total anomalous pulmonary venous return, multiple suprasternal and subcostal veins

will usually demonstrate the location of the connection between the pulmonary venous confluence and the systemic veins.

Pulsed, range-gated Doppler sampling allows detection of flow in the ductus if present and allows differentiation of venous from arterial structures in complicated cases.[128] Insufficiency of AV valves can be detected and semiquantitated. If pulmonary stenosis is severe, Doppler interrogation will allow differentiation of stenosis from atresia.

Color flow mapping is quite useful, providing similar information to that obtained by pulsed, range-gated Doppler but providing much more information in each frame. The duration of the examination is reduced, and unsuspected abnormal flows may be detected.

Continuous-wave Doppler combined with imaging is of great utility, allowing quantitation of gradients across valves, ventricular septal defect, pulmonary venous connections, and coarctations. The combination of continuous wave, two-dimensional structural, and color flow mapping obtained simultaneously is very important in these hearts with highly variable structural anatomy and many high-velocity jets.

Usually, the structure and physiology are well demonstrated by these noninvasive techniques and catheterization can be directed to obtaining information not available by echocardiography. The fluoroscopy time required may be reduced because of echocardiography, and the angled views can be planned according to the form of the individual heart and the information required. In many cases, catheterization can be safely postponed and done on a larger, less fragile child.

Quantitation of two-dimensional images has been used to assess ventricular function in patients with double inlet.[129] The authors found global indices of ventricular function to be remarkably normal. End diastolic volumes were large, as might be expected. Wall-motion abnormalities were common, although there was no consistent pattern, timing, or location. Wall-motion abnormalities were unrelated to age, hematocrit, or previous palliative surgery. This observation raises questions about the usefulness of M-mode measurements of shortening fraction in these patients. The relatively normal function contrasts with reports concerning tricuspid atresia[130,131] and with angiographic studies[132] in single ventricle.

OTHER IMAGING MODALITIES

Magnetic resonance imaging presently[133] provides little information not obtained more quickly, precisely, and cheaply by two-dimensional and Doppler echocardiography. This modality may be useful in older patients with poor windows for echocardiography. Imaging of deep, static structures, such as systemic and pulmonary veins, may be improved using magnetic resonance imaging. Coarctation may be evaluated, and these images may be especially helpful in following patients postoperatively.

Radioisotope techniques may be used to assess ejection fraction. However, in children we usually evaluate ventricular performance with echocardiography,[129] to avoid radiation exposure. The advantage to isotope techniques is that no assumption about the geometry of the ventricle is required. These techniques have been applied to patients with tricuspid atresia[130] and to those with single ventricle.[134]

CARDIAC CATHETERIZATION

Cardiac catheterization should be planned on the basis of information obtained by two-dimensional and Doppler echocardiography. The timing of the catheterization may be dictated by the need for intervention in the newborn period, when balloon atrial septostomy, shunting, or banding is necessary.

At catheterization the systemic venous anatomy should be explored. Usually the presence of bilateral superior vena cavae is demonstrated echocardiographically, but it is helpful to document the catheter course into each. When the venous drainage from the lower half of the body enters the heart via an azygos vein continuation to the superior vena cava, this is usually strongly suspected from echocardiography. In the catheterization laboratory, the catheter in the vein behind the heart may appear to be within the heart. An inability to bring the catheter in an anterior direction, and identical saturations below, "within," and above the heart should suggest the diagnosis. A small injection of contrast material by hand will usually clarify the situation. A deflector wire will help in making the curve anteriorly and downward into the heart. In newborns, especially, this tight curve makes further manipulation of the catheter within the heart more difficult. Careful measurement of oxygen saturation will help document anomalous connection of the pulmonary veins if present. When the site of anastomosis is seen echocardiographically, it may be possible to pass the catheter into the pulmonary venous confluence. Pressure measurements and angiography here will allow an assessment of the presence and degree of obstruction.

Within the heart both atria can commonly be entered, but an intact atrial septum may prevent easy passage of a catheter into the pulmonary venous atrium. If the AV valve draining the pulmonary venous atrium is suspected to be stenotic, transseptal technique may be indicated.

The dominant chamber can almost always be entered. The nondominant chamber can also frequently be entered and this should be done when possible to document any pressure gradient across the ventricular septal defect. If echocardiography has suggested a small ventricular septal defect, then measurements should be taken quickly. Angiography, if necessary, should be performed, and the catheter removed. In the setting of a restrictive ventricular septal defect, the catheter may be large enough to reduce significantly the flow through the ventricular septal defect into the aorta or pulmonary artery.

Both the aorta and pulmonary arteries can often be entered.[62] There may be streaming of arterial and venous blood within the heart so that pulmonary and aortic oxygen saturations may differ significantly.[135–138] When there is a large atrial septal defect, total anomalous pulmonary venous connection, atresia of one AV valve, or pulmonary atresia, total mixing of systemic and venous blood generally occurs (36% of the patients in Macartney et al.'s report[135]). Streaming was favorable with aortic saturation higher than in the pulmonary artery in 52%. Unfavorable streaming occurred in 12%. In one patient an aortic saturation of 97% (pO_2 86 mm Hg) was present. However, the primary determinant of the systemic oxygen saturation is the amount of pulmonary arterial blood flow relative to the systemic blood flow (Qp/Qs). This accounted for 79% of the variability in systemic arterial saturation in Macartney's experience.

When the pulmonary artery can be entered, pressure measure-

ment allows an assessment of the degree of protection of the pulmonary vasculature. In many of these hearts the specialized conduction tissue runs around the anterior margin of the pulmonary valve annulus and complete heart block (usually temporary) may be provoked while manipulating the catheter into the pulmonary artery.

When severe stenosis or atresia of the AV valve draining the pulmonary venous atrium is suspected, catheterization should be performed in the neonatal period. The atrial septum is "softer" at this time and the likelihood of successful balloon atrial septostomy is greater. If the problem is not recognized until later in life, a blade[139] and balloon atrial septostomy may be attempted. The gradient between right and left atria must be abolished to decrease the symptoms of pulmonary venous hypertension.

Presently, inadequate pulmonary blood flow is managed by a surgical aorticopulmonary shunt. When pulmonary blood flow is limited by valvular pulmonary stenosis, it may be possible to use balloon techniques to relieve the stenosis partially and thus improve pulmonary blood flow without an operation. When pulmonary atresia is present and the ductus arteriosus has remained patent past the newborn period, but has shown evidence of constriction in its midportion, balloon ductal dilation may avoid or postpone the necessity for a shunt. We have successfully applied this technique to one patient with discontinuous pulmonary arteries arising from bilateral ductus. Nihill and coworkers have also successfully utilized balloon ductal dilation to avoid aorticopulmonary anastomosis. (Personal communication).

ANGIOGRAPHY

Angiography has played a major role in the development of our understanding of hearts with univentricular AV connection.[6,30,40,62,140–146] Quantitation of ventricular volume has been reported using angiographic techniques.[147–150] While echocardiography has emerged as a powerful tool for evaluating the anatomy of these hearts, angiography remains essential for the evaluation of details less well demonstrated echocardiographically. Angiography should be preceded by a complete echocardiographic examination. Often this is most efficiently obtained at the time of catheterization, while the child is sedated. The physician performing catheterization and angiography, thus guided, may use limited fluoroscopy time and contrast material to obtain essential information.

Anteroposterior and lateral cineangiography will provide delineation of many of the required details.[135,141] Axial angiography[151–156] allows clearer demonstration of AV valve anatomy, tiny ventricular chambers, outflow tracts and peripheral pulmonary arteries. The two most important views are the "four-chamber" view and the long axial oblique view.

The four-chamber view is obtained by sitting the patient up 35 to 45 degrees then raising the left shoulder by 35 degrees. The patient is then angled on the table so that the long axis of the heart becomes more parallel to the table. A similar relative position of tubes and patient can be obtained using a double C arm, however, the head tends to be more in the way than if the patient is sitting up and the neck hyperextended. In a biventricular heart, the four-chamber view profiles the inlet septum and separates the atria and ventricles. In hearts without an inlet septum the AV valves are usually well seen and their relation to the trabecular septum may be demonstrated. In addition, the left pulmonary artery is especially well defined by the anteroposterior tube in the four-chamber view. When abnormalities of the proximal left pulmonary artery are suspected this view should be used; it requires greater penetration of the liver than the other views. The liver collects contrast material and becomes more difficult to penetrate, requiring higher kilovoltage, with successive injections. The least Compton scatter and therefore the sharpest images will be obtained if this view is used for the first injection of contrast.

The long axial oblique projection applied to the normal heart gives information about the left ventricular outflow tract, and the more anterior portion of the ventricular septum. In the hearts with univentricular AV connection and normally related ventricles this view will profile ventricular septal defects well.

When echocardiography suggests dominant left ventricle with right-hand architecture, the initial injection may be made with the catheter in the left ventricle and the patient turned to provide the four-chamber view. If the AV valve anatomy is well demonstrated by echocardiography and there is no indication of left pulmonary artery abnormality, the standard anteroposterior view may be used first. This is especially true if there is severe pulmonary stenosis or atresia and knowledge of the great vessel anatomy is required to plan a shunting procedure. Finally, the long axial view will usually demonstrate the ventricular septal defect or ventricular septal defects and any right ventricular outflow obstruction (Fig. 74–11).

When there is a dominant left ventricle and the ventricles are inverted, the standard frontal and lateral views will provide excellent visualization of the ventricular septal defect, or defects, and the subarterial region of the right ventricle (Fig. 74–12). If there is a question concerning the AV valves the four-chamber view should be utilized and, if needed, should be done as the first injection. Though injection into the left ventricle will usually show structures well, the catheter can usually be manipulated through the ventricular septal defect and an injection into the right ventricle can be made. When there is a restrictive ventricular septal defect, a right ventricular injection may be necessary to force enough contrast material into the aortic arch to allow accurate diagnosis of coarctation or interruption.[157]

When a dominant right ventricle is present with a posterior nondominant left ventricle both four-chamber and long axial oblique views should be performed. When the left ventricle is leftward (normally related ventricles) it is usually best seen in the frames obtained by the lateral camera when the patient is positioned for the four-chamber view (Fig. 74–13). When the left ventricle is rightward (inverted ventricles), it is usually best seen by the anteroposterior camera when the patient is positioned for the long axial oblique view.

When echocardiography fails to demonstrate a second ventricular chamber, the initial view should be the four-chamber, followed if necessary by the standard frontal/lateral, and long axial oblique views (Fig. 74–14).

These views are recommended to demonstrate the ventricular and AV valve anatomy. In the fragile newborn we are often more interested in the anatomy crucial to planning a shunt procedure than anatomic details required for more definitive surgery. We may alter views to better demonstrate arch and pulmonary artery anatomy, and may defer some injections until later infancy or childhood.

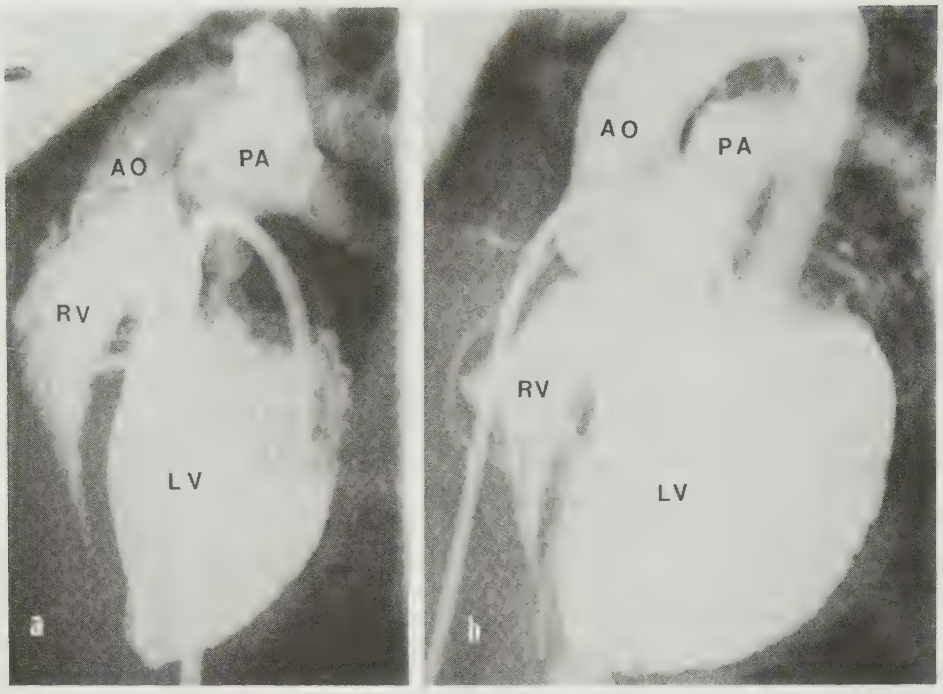

Fig. 74–11. Angiogram of a) double inlet to dominant left ventricle with right-hand architecture and ventriculoarterial discordance. The ventricular architecture is indistinguishable from a patient with b) classic tricuspid atresia. AO = aorta; PA = pulmonary artery; RV = right ventricle; LV = left ventricle.

NATURAL HISTORY

Case reports document survival into adulthood[158–161] and female patients have experienced successful pregnancies.[162,163] The most detailed information concerning the prognosis of patients with single ventricle not operated on is reported by Moodie et al.[101] These patients were in late childhood at the time of diagnosis and therefore had survived the high-risk neonatal period. Eighty-one percent of 83 patients had an outlet chamber (type A) and 19% did not (type C). Seventy-eight percent had no associated noncardiac lesions. Seven percent had asplenia. The most common associated cardiac lesion was pulmonary stenosis, present in 37% of patients with type A morphology. Most patients had exercise intolerance and cyanosis.

Fifty percent of patients with type A morphology were dead within 14 years after diagnosis, a death rate of 4.8% per year. For type C anatomy the prognosis was worse; 50% of patients died within four years of diagnosis. Of the patients in New York Heart Association (NYHA) class I or II at initial diagnosis, 34% with type A and 12% with type C were in class III or IV or had died at followup. Three patients had episodes of supraventricular tachycardia during followup and complete heart block developed in no patient. However, dysrhythmia or sudden unexplained death was the most common cause of death. Other causes included congestive heart failure, thrombotic occlusion of the pulmonary valve, brain abscess, pancreatitis, cerebral infarction, cerebral embolus and hemorrhage, and pulmonary embolus. In a companion study of patients give palliative treatment the causes of death were similar but also included endocarditis. Though palliation improved symptoms, survival was not greatly improved.

Atrioventricular valve insufficiency often appears and progresses over the first two or three decades in even patients with good palliation. This is presumed to be secondary to the left ventricular volume overload imposed by the need for a pulmonary blood flow of about twice normal. The tendency toward progression of subaortic stenosis in some patients is discussed more fully in the section of palliative surgery.

SURGERY

The dismal natural history for this group of patients has provided the motivation for the development of a number of palliative procedures and two more radical ''curative'' procedures.

Palliative Procedures

Palliative procedures include systemic-to-pulmonary-artery shunting, pulmonary artery banding, atrial septectomy, atrial switch procedures, superior-vena-cava-to-right-pulmonary-artery anastomosis, and a number of procedures to relieve subaortic obstruction. The latter include left-ventricle-to-descending-aorta conduits, resection of septal muscle to enlarge the interventricular communication, and anastomosis between the main pulmonary artery and the ascending aorta, usually combined with systemic-to-pulmonary-artery shunting. The goal in each is to provide relief of current symptoms and to allow survival to an age when a more ''curative'' procedure, if possible, may be performed with lower risk. Ideally, structural and functional changes induced by the palliative procedure should not adversely affect the risk of a subsequent ''curative'' procedure. It is therefore important to decide early in life which ''curative'' operations are possible for a given patient in order to establish the goals of early palliative surgery. Some patients will have an anatomy or physiology that precludes a more ''curative'' procedure. For these patients the palliative procedure will be the only surgical option available.

Problems that force palliation include cyanosis when pulmonary blood flow is restricted or streaming is unfavorable, congestive heart failure and the threat of pulmonary vascular obstructive disease when there is no restriction to pulmonary blood flow, pulmonary venous hypertension when the atrial septum is relatively intact and there is left AV valve stenosis or atresia, and subaortic

obstruction usually secondary to a restrictive ventricular septal defect.

Operations to Increase Pulmonary Blood Flow

Kreutzer et al.[164] reported successful resection of pulmonary stenosis as palliation for three patients with reduced pulmonary blood flow. Each was alive six years postoperatively and two of the three were functionally normal. This method of increasing pulmonary blood flow involves an open procedure, and control of the amount of additional blood flow provided seems less precise than with a classic or modified Blalock-Taussig anastomosis. The possibility of partially relieving valvular stenosis by balloon catheterization techniques has the advantage of avoiding an operation, but the similar disadvantage of less control over the degree of shunting.

Systemic to Pulmonary Artery Shunts

Early reports[165–168] suggest mortality rates for shunt procedures performed on patients with single ventricle ranging from 8 to 50%. Villani et al.[165] reported a 20% mortality rate for shunting using Waterston shunts in young infants and classical Blalock-Taussig shunts for other children. If patients with major associated anomalies were excluded, the mortality was 8%, similar to the result in classic tricuspid atresia in the same period. Shunting was necessary twice as often as banding in this set of patients.

Crupi et al.[104] reported on a group of young patients (median age at surgery, 8.5 months) palliated with modified Blalock-Taussig or classic Blalock-Taussig shunts with an operative mortality of 8%. Actuarial survival of their group (including eight patients with successful pulmonary artery banding) was 80% at 10 years. Mazzucco et al.[169] reported 8% mortality with the same shunts, while neither of the two patients treated with a Potts or Waterston anastomosis survived.

Stefanelli et al.[41] and Kirklin and Barratt-Boyes[170] reported a 2% (confidence interval, 0.3 to 8%) operative mortality (1 death in 45 patients) for classic Blalock-Taussig or modified Blalock-Taussig shunting. Of the 45 survivors, 15 underwent at least one subsequent operation. During the same period, 18 nonclassic shunts were performed with 5 operative deaths (28% mortality, confidence interval, 16 to 43%). Actuarial five-year survival for a classic shunting procedure was 85%.

The long-term followup of these younger patients contrasts with the result when an older group is followed. Moodie et al.[110] reported on a large group of patients with a mean age at diagnosis of 10 years. Shunts included classic Blalock-Taussig, Potts, Waterston, and Glenn anastomoses. The estimated five-year survival rate (after diagnosis, not necessarily after procedure) in patients with an outlet chamber was 72%, and in patients without an outlet chamber 54%. Causes of death in 33 patients who had palliative surgery (shunting, banding, and/or septectomy) included conges-

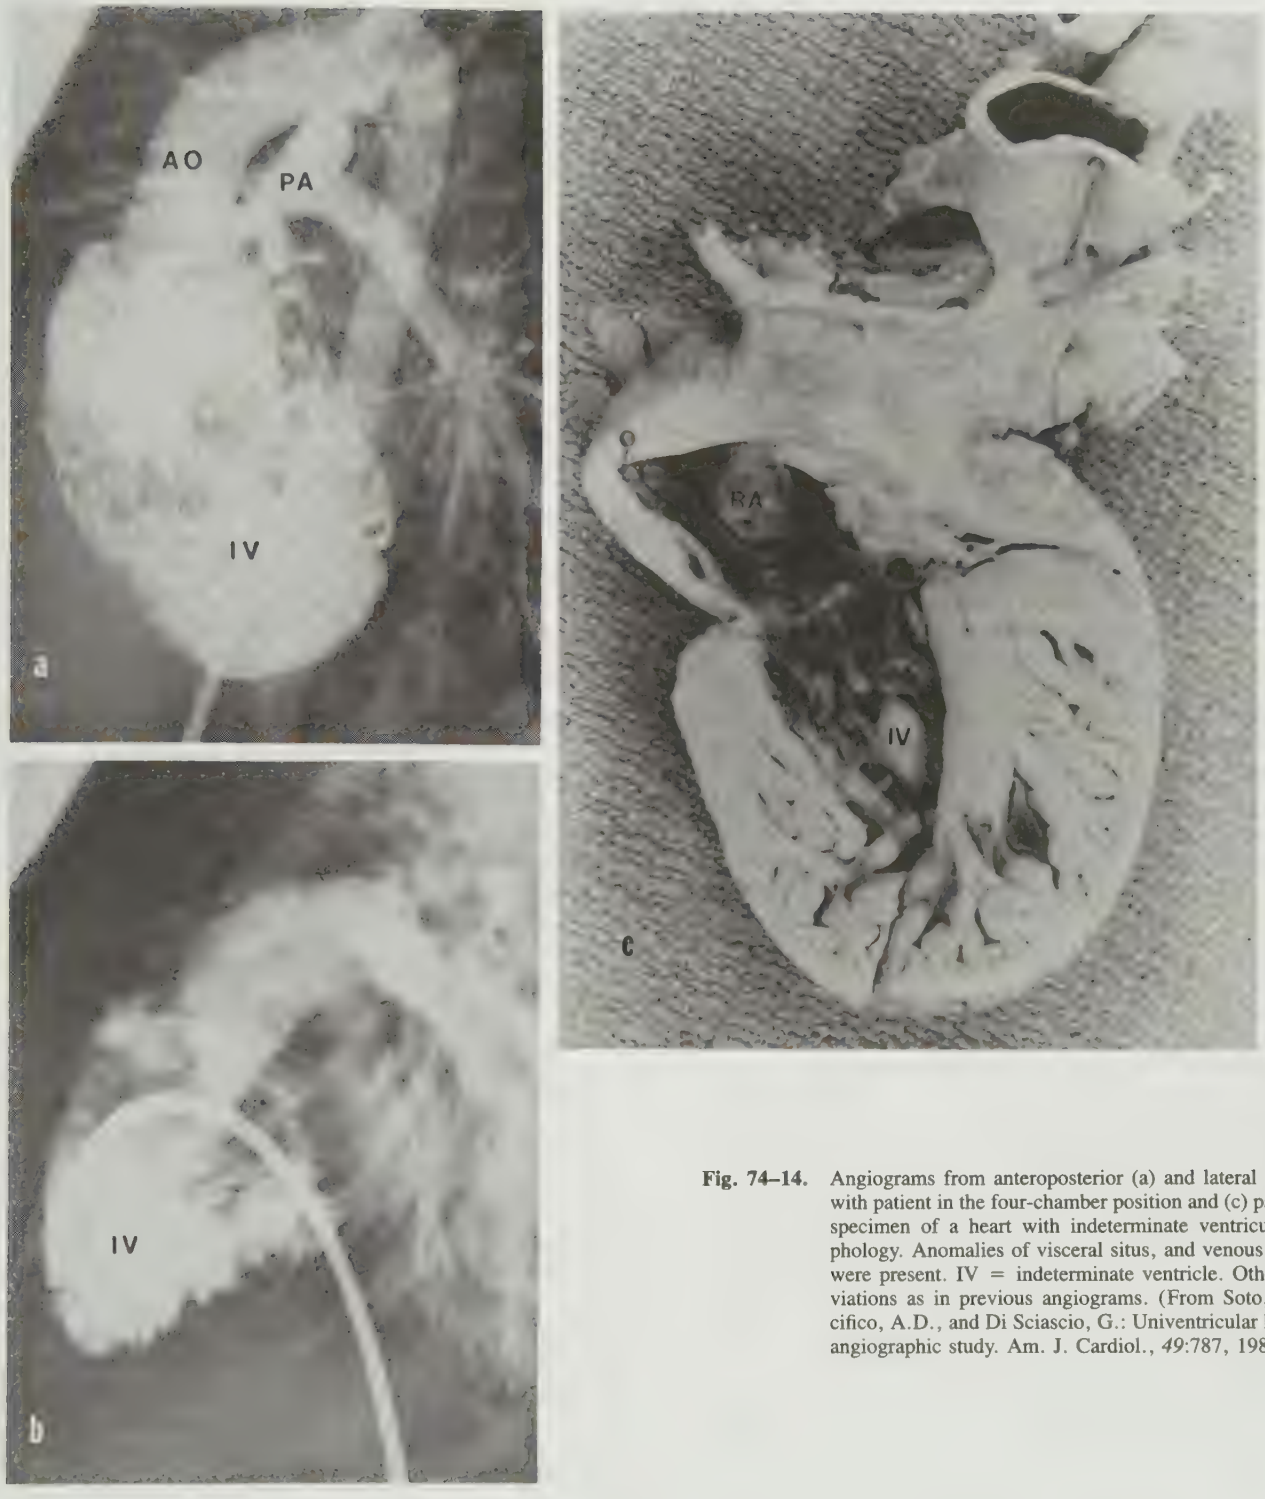

Fig. 74–14. Angiograms from anteroposterior (a) and lateral (b) tubes with patient in the four-chamber position and (c) pathologic specimen of a heart with indeterminate ventricular morphology. Anomalies of visceral situs, and venous drainage were present. IV = indeterminate ventricle. Other abbreviations as in previous angiograms. (From Soto, B., Pacifico, A.D., and Di Sciascio, G.: Univentricular heart: An angiographic study. Am. J. Cardiol., *49*:787, 1982.)

tive heart failure, dysrhythmia or sudden unexplained death, acute cerebral events, pneumonia, hypoxemia due to an occluded shunt, and endocarditis. Functional class I or II at diagnosis did not ensure longterm survival.

Taussig[171] reported followup of up to 27 years on 24 patients who underwent a Blalock-Taussig anastomosis for a single ventricle. The actuarial survival curve (Fig. 74–15) drawn from her data shows a 10-year survival for hospital survivors of 72% and a 20-year survival of 50%.

In summary, it is possible to perform classic and modified Blalock shunts on this group of patients with low operative risk. These shunts allow survival and growth of pulmonary arteries. Patients who are not candidates for modified Fontan or septation operations may remain palliated for many years, though second shunting procedures may be necessary. The importance of precise diagnosis prior to a shunting procedure is exemplified by two patients[104] with unrecognized total anomalous pulmonary venous return who died from pulmonary edema following shunting.

Pulmonary Artery Banding

Pulmonary artery banding was required much less frequently than shunting.[104,110,170,172] Dooley et al.[173] reported 11 survivors of 20 patients undergoing banding for a single ventricle. Lower early mortality rates have been reported by others.[104,165,169] Possible complications include inadequate reduction of pulmonary artery pressure with resulting pulmonary vascular obstructive disease,[169] distal migration of the band with resulting distortion of the proximal branch pulmonary arteries, and massive ventricular hypertrophy with resulting obstruction at the level of the ventricular septal defect.[174–177] Of the eight patients at risk in the report of Crupi et al.[104] only two developed subaortic obstruction. In the larger series of Freedom et al.,[176] 72% (31 of 43 patients) banded early in life (mean age at banding, 0.23 year) developed subaortic obstruction. In the subgroup of 32 patients with dominant left ventricle and ventriculoarterial discordance, 27 or 84% developed stenosis. The mean age at diagnosis of stenosis was 2.5 years.

Patients have been reported in whom an appropriate narrowing of the pulmonary artery failed to protect the pulmonary vasculature.[178,179] Late results in older patients reported by Moodie et al.[110] suggest a mortality rate five years after diagnosis (not necessarily after banding) of 32%. The causes of late mortality are listed in the section on shunts and are not broken down into banding versus shunting.

While the early operative risk is low, and adequate protection of the pulmonary vascular resistance may be obtained, the adverse effects on the ventricular septal defect and ventricular compliance have prompted the suggestion by Freedom[180] that pulmonary artery banding should not be performed as palliation when "curative" operation is planned and the anatomy is such that subaortic obstruction seems likely to develop.

Atrial Septectomy

Atrial septectomy is mentioned in several reports[110,165,169,181] with few cases and variable results. Stefanelli et al.[41] reported no hospital deaths in 14 patients who underwent a Blalock-Hanlon operation with or without associated closed procedure. Actuarial survival at 10 years was 75%. Five of the patients underwent at least one subsequent operation. Septectomy is usually undertaken to relieve left atrial hypertension when there is a restrictive atrial septal defect and stenosis or atresia of the valve draining the pulmonary venous atrium. In patients with unrecognized obstruction to the outlet of the pulmonary venous atrium shunt procedures may precipitate pulmonary edema. It is therefore important to recognize the need for septectomy at the time of initial diagnosis so that shunt and septectomy, if necessary, may be performed via the same thoracotomy. It has been suggested that septectomy might improve mixing in hearts with unfavorable streaming and intact atrial septum, but conclusive data are not available. It has also been suggested that in patients with unfavorable streaming a pal-

liative Mustard or Senning operation might improve saturations.[182,183]

Glenn Shunt

While most patients are well served by classic or modified Blalock-Taussig anastomoses, there are patients who may be better served by a superior-vena-cava-to-right-pulmonary-artery anastomosis.[184–190] This procedure achieves an increase in effective pulmonary blood flow without placing an increased volume load on the ventricle.[191] This may be advantageous in the presence of significant AV valve insufficiency or mild ventricular dysfunction. When there is severe proximal right pulmonary artery stenosis that would be difficult to relieve at the time of a Fontan-type repair, a Glenn shunt may be used[189] in conjunction with a right-atrium-to-main-pulmonary-artery anastomosis to achieve a similar physiology. In fact, Fontan and Baudet[11] used a Glenn shunt in their first reported case and 17 of 100 patients reported on in 1983 had undergone previous Glenn shunting.[192] Anastomosis of the transected right pulmonary artery to the side of the superior caval vein, which is left in free communication with the right atrium, has been used.[193] This has the theoretical advantage of allowing the right lung (which receives two thirds of the total ventilation) to receive flow from both the upper and lower venous returns.

Hopkins et al.[194] reported use of a modification of the Glenn shunt in which the right pulmonary artery is not transected but left in continuity with the main pulmonary artery. Such a bidirectional shunt has the advantage of allowing the larger circulation of the right lung to receive blood from both the superior and inferior caval veins after the Fontan procedure. This bidirectional cavopulmonary shunt has been applied as a palliative procedure as well as at the time of Fontan operation. Twelve of 21 patients had classic tricuspid atresia and 9 had other forms of univentricular AV connection. All 12 patients undergoing palliative operation survived and were improved. Five subsequently underwent a Fontan operation, with no deaths. When the shunt was performed at the time of Fontan operation there were two early deaths and one patient died suddenly later.

Operations to Relieve Subaortic Stenosis

Subaortic stenosis is an ominous finding. Congenital presence of subaortic stenosis at the level of the ventricular septal defect has been described.[4] Early development of subaortic stenosis in the presence of congenital pulmonary stenosis has been documented as well.[177,195] As mentioned in the section on banding, the progression of stenosis is accelerated by banding.

When subaortic stenosis is present with or without previous banding,[196] a number of operations have been attempted to achieve palliation. Penkoske et al.[197] reported success in three patients treated by enlargement of the ventricular defect, in two patients with enlargement of the ventricular septal defect and placement of a left ventricular to descending aorta conduit, and in one patient by creation of an aortopulmonary window proximal to a previously placed pulmonary artery band. There were only 9 survivors of 31 patients who developed subaortic stenosis.

In a child with excessive pulmonary blood flow a modification[198] of the Norwood[199] procedure with transection of the main pulmonary artery, anastomosis of the proximal pulmonary artery to the aorta, and placement of a modified (5-mm Gore-Tex) Blalock-Taussig shunt to the distal pulmonary arteries has been performed. Alternatively, a graft has been placed from the proximal pulmonary artery to the descending aorta with banding of the proximal pulmonary artery.[200]

Lin et al.[201] reported on eight patients with subaortic stenosis treated by end-to-side anastomosis of the main pulmonary artery to the ascending aorta (Fig. 74–16). Preoperative gradients ranged from 10 to 80 mm Hg. Two operations were performed as palliative procedures within the first six months of life, while the other six were performed as a part of a definitive Fontan-type repair. The single death occurred following a palliative procedure performed at four months of age.

Barber et al.[202] described one patient who died following palliation with pulmonary-artery-to-aorta anastomosis and shunt. Four other patients, three of whom died, were treated similarly at the time of a Fontan-type repair.

Jonas et al.[203] described three patients successfully palliated by anastomosis of the pulmonary artery to the ascending aorta with placement of a shunt. Subsequently, Rothman et al.[195] described, more fully, experience at the Boston Children's Hospital with this problem. Of four children treated with a left-ventricle-to-descending-aorta conduit none survived. Four of the seven who had enlargement of a restrictive ventricular septal defect survived, but only one of four had adequate relief of stenosis and postoperative heart block was common. Six of 13 patients undergoing main pulmonary-artery-to-ascending-aorta connections survived and four have successfully undergone a modified Fontan procedure, while two await operation. The overall survival rate for all procedures was 42% and no patient with a gradient greater than 77 mm Hg survived any procedure. On the basis of their small but dismal experience with enlargement of the ventricular septal defect, they have chosen to palliate with a pulmonary-artery-to-aorta anastomosis. Whether patients palliated in this manner will fare better with subsequent septation or a modified Fontan operation remains to be seen.

"CURATIVE" PROCEDURES

Fontan–Kreutzer Operation

The original papers of Fontan[11] and Kreutzer[12] and their colleagues established the concept of using the single ventricle in tricuspid atresia to generate systemic blood flow while allowing pulmonary flow to occur directly from the right atrium to the pulmonary artery without an interposed ventricle. This concept was extended to the treatment of other forms of univentricular AV connection by Yacoub and Radley-Smith[13] and others.[204–211] As with the application of this concept to classic tricuspid atresia, the exact surgical details of the right-atrium-to-pulmonary-artery connection have undergone modifications.[212] While early operations were performed using valved conduits, most are presently done by direct anastomosis[213] and if necessary roofed with Dacron or Gore-Tex[170] or pericardium.[214] The major considerations presently recognized include creation of a generous anastomosis between the atrium and pulmonary artery, careful avoidance of compression of the anastomosis by sternum or thymus, and avoidance of the sinus node artery on the roof of the atrium

In cases with two competent and nonstenotic AV valves the right valve may be closed by direct suture of valve leaflets[215] or a patch sewn to valve tissue or to atrial myocardium several mil-

Cardiol., *7*:617–624, 1986.)

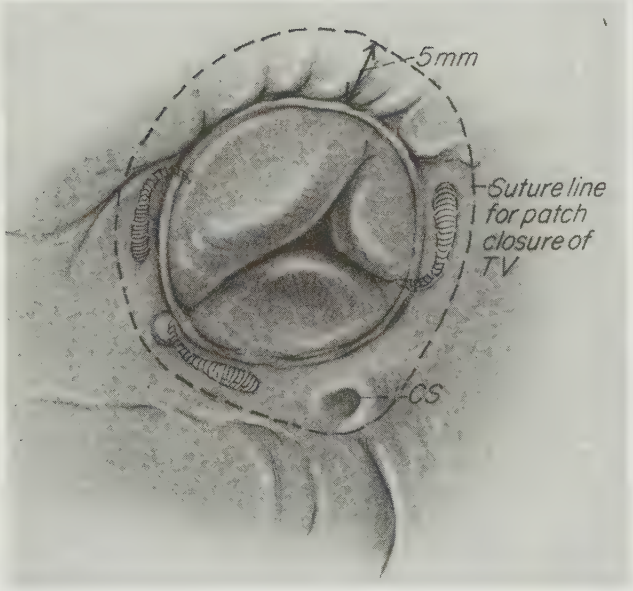

Fig. 74–17. Technique for closing the right atrioventricular valve with Fontan-type operation for single ventricle. TV = tricuspid valve; CS = coronary sinus. (From Kirklin, J.W., and Barratt-Boyes, B.G.: Univentricular atrioventricular connection (single ventricle). *In* Cardiac Surgery. New York, Wiley, 1986.)

limeters outside the annulus (Fig. 74–17). The latter technique is presently preferred, since dehiscence is less likely and AV block due to damage of the AV node is usually avoided.[170,204,214,216] Closure of the right AV valve is mandatory if the valve is insufficient. If both valves are competent, then a baffle may be placed in the atrium leaving both valves receiving pulmonary venous blood and allowing egress into the ventricle (Fig. 74–18). This type of connection must be used if the left AV valve is absent or stenotic. If the atrial baffle is too redundant it will obstruct one pathway or the other.[216] More recently, a technique has been devised using part of a woven Dacron conduit as one wall and the lateral atrial wall as the other to create a tubular conduit to direct the inferior caval flow to the roof of the atrium.

The problem of subaortic stenosis, usually at the level of the ventricular septal defect, has been mentioned in the section on palliative surgery. Main pulmonary-artery-to-aorta anastomosis[217] has been used at the time of modified Fontan operation.[13,181,197,201,202,218,219] Enlargement of the ventricular septal defect also has been performed concomitantly with a modified Fontan procedure. Clearly, the presence of a significant gradient is associated with a hypertrophied, noncompliant ventricle and high operative mortality.[220] The operative mortality in the group of cases from the literature summarized by Barber et al.[202] was 60% (9 of 15 patients). In their own experience, the surgical mortality rate was 56% (10 of 18 patients), of which 13 had a modified Fontan procedure, 3 a septation, and 1 an aorta-to-pulmonary-artery anastomosis combined with enlargement of the ventricular septal defect. Neither patient with aorta-to-pulmonary-artery anastomosis survived. Those who did survive were usually symptomatic.

The series reported by Lin et al.,[201] in which five of six patients undergoing pulmonary-artery-to-aorta anastomosis with modified Fontan operation survived, is a source of some optimism.

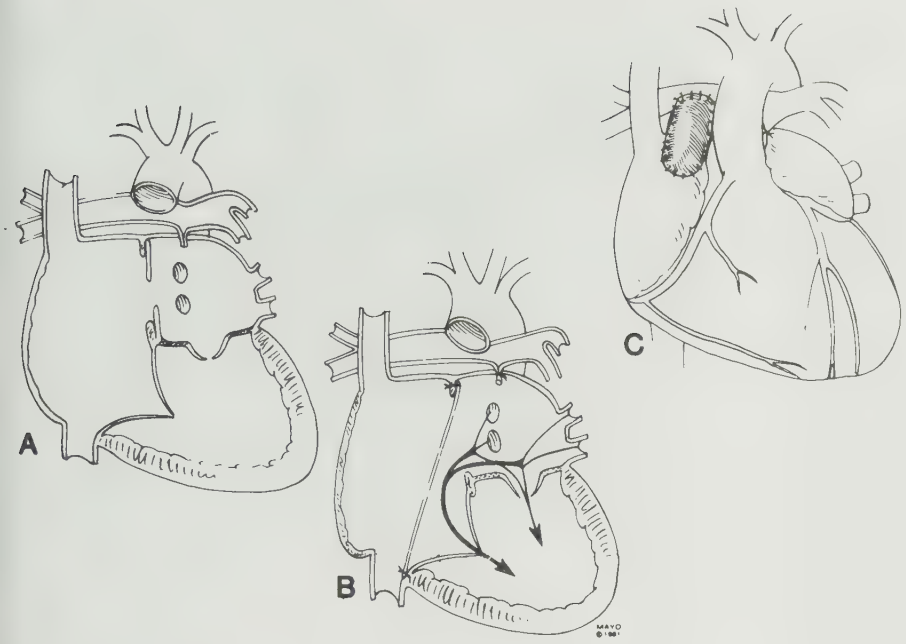

Fig. 74–18. Position of the baffle in hearts with a stenotic left atrioventricular valve. Note the potential for bulging of the baffle and partial obstruction of the right atrioventricular valve. (From Danielson, G.K.: Surgical management of double inlet ventricle. *In* Double Inlet Ventricle. Edited by R.H. Anderson, G. Crupi, and L. Parenzan. Tunbridge Wells, Kent, Castle House Publications, 1987.)

Danielson[214] reported an early mortality of 10% for a modified Fontan procedure for double-inlet left ventricle when all 10 ideal criteria[221] were met. Mortality was greater than 50% when three or more criteria were not met. He comments that only one fifth of his patients fulfilled all criteria. The absence of sinus rhythm was not found to be a contraindication to operation[222] and permanent pacing techniques have been applied postoperatively.[110,223,224] The two most important criteria require normal pulmonary arteriolar resistance, and adequate size and distribution of the pulmonary arteries. In the Mayo Clinic experience,[214] the operative mortality has improved from 30% for the first 92 patients with double-inlet left ventricle to 9% for the 57 patients operated on between April 1982 and April 1984. This improvement may be due to better selection of patients or better operative and postoperative techniques.

The overall 29% mortality in Kirklin and Barratt-Boyes' experience[170] using a modified Fontan procedure for a single ventricle is similar to that at the Mayo Clinic and other published experiences.[204,206,208] More recent experience from January to November 1983 with a mortality rate of 7% (confidence interval, 1 to 22%) would support the idea that results from this procedure are improving.

For the Fontan procedure in general, death after hospital discharge is uncommon and actuarial late survival of hospital survivors is 92%. If hospital deaths are included in the actuarial survival, survival at 5 years has been 71% (95% confidence, ±6%), and with current techniques is anticipated[170] to approach 90%.

Late problems include ventricular dysfunction,[225] AV valve insufficiency, atrial arrhythmia, and protein-losing enteropathy.[214] Catheterization has documented an improvement in mean left ventricular end diastolic pressure, presumably as a result of relief of volume overload. More than 90% of survivors[170,208,214] are in NYHA class I or II. Exercise testing in survivors was normal in Kreutzer's experience[164] and mildly subnormal in the Mayo Clinic experience.[214,226,227]

While no large series of patients with significant systemic and pulmonary venous anomalies treated with Fontan-type operation has been reported, case reports of success[228–230] have been reported. Valve replacement was necessary in some cases with insufficient common AV valve. Successful pregnancy was reported[229] in one such patient six years postoperatively.

Septation

A case of single ventricle encountered unexpectedly (preoperative diagnosis was corrected transposition and ventricular septal defect) at the Mayo Clinic in 1956 was repaired by dividing the ventricle.[231] The patient died six months after surgery, presumably due to a Stokes–Adams attack. In the early 1970s several reports of success[78,232–234] prompted renewed interest in this approach. The right atrial approach to septation was suggested and applied.[235]

Overall operative mortality was high during the early experience: 47% (21 of 45 patients) at the Mayo Clinic[111] and 44% (7 of 16 patients) in the University of Alabama Birmingham[236] experience. Operative technique improved with transatrial approach, or "fish-mouthed" ventriculotomy to avoid coronary artery injury.[42] Small ventricular size and presence of outlet obstruction emerged as risk factors in the University of Alabama Birmingham experience. The Mayo Clinic experience identified preoperative congestive heart failure, and previous palliative surgery as significant risk factors. Polycythemia and preoperative or postoperative complete heart block were not found to be risk factors. Operative mortality was increased if there was need for valve replacement or placement of a valved external conduit. Complete heart block was present preoperatively in 3 of 32 patients, and postoperative heart block occurred in 25 of 28 patients at risk in the University of Alabama Birmingham experience.[170] Though the differences in survival for different morphologic subgroups have been too small to prove statistical significance,[11,170] no survivors were present among the anatomic subgroups with no outlet chamber in the Mayo Clinic experience. Reoperation was required for patch dehiscence and valve dysfunction.[237] There were several late

postoperative sudden deaths and only 7 of 16 late survivors were asymptomatic. Multivariate analysis of the Mayo Clinic experience identified a subgroup of 11 patients who had good results from operation—82% survival. These patients had a subaortic chamber to the left, no previous congestive heart failure, no previous palliative operation, no profound polycythemia, and ranged from 5 to 15 years of age at the time of operation. On the basis of these findings, the Mayo Clinic established the practice of performing modified Fontan operation when possible and reserving septation for patients with modestly elevated pulmonary vascular resistance.

Stefanelli et al.[41] described a similar outcome for an ideal set of patients with a large left ventricle, normal situs, and left-sided subaortic chamber with no associated defects. Among these, there were no hospital deaths and 77% (confidence interval, 59 to 90%) were alive after a median followup of 2 years. There were two late sudden deaths. Two patients in this group required reoperation for patch dehiscence. All of the surviving patients were in NYHA class I or II. Detailed hemodynamic studies[238] support the possibility of good functional status after septation, as do animal studies[239–241] in which the septum was replaced without detriment to ventricular function.

In 1984, Ebert[103] reported a two-stage approach, which he applied to hearts with "common ventricle." In infancy, a patch is placed at the apex and a second patch between the AV valves. Widely spaced sutures are used. A pulmonary artery band is placed. A second stage is undertaken 6 to 18 months later, at which time the "ventricular septal defect" is closed and the band removed. All four patients survived with sinus rhythm. It is uncertain if the morphology in these patients would have led to heart block if a single-stage repair had been undertaken. Forthcoming further experiences will certainly be of great interest.

Current operative technique has been outlined by Pacifico et al.[242,243] (Fig. 74–19). The location of the suture line superiorly is dictated by the location of the aterial valves and inferiorly by the location of the papillary muscles and chordal apparatus, thus the surgeon has little control over the amount of ventricle allocated to the right and left sides. The size of the patch is critical, since too large a patch will bulge and possibly obstruct the right outflow. Too small a patch will be more likely to dehisce. If the great vessels are not appropriately placed for a straight patch, a spiral patch may be used. Alternatively, a straight patch has been used with concomitant atrial switch with good result.[242] Intraoperative mapping of the conduction system has been used, but this is not possible when repair is performed through the atrium.

Subpulmonic stenosis may be resected in many patients but an external valve conduit may be required to connect the new "right" ventricle to the pulmonary arteries. Operative mortality is higher (67% with 44 to 85% confidence interval) when a conduit is required.[242]

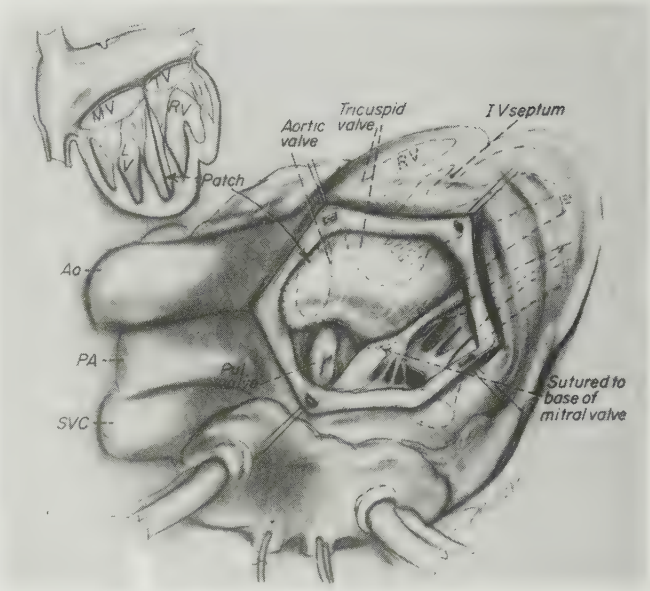

Fig. 74–19. Location of the patch in the septation operation for double-inlet left ventricle with left-hand architecture and ventriculoarterial discordance. MV = mitral valve; TV = tricuspid valve; RV = right ventricle; LV = left ventricle; IV = interventricular; Ao = aorta; PA = pulmonary artery; Pul = pulmonary; SVC = superior vena cava. (From Pacifico, A.D., Soto, B., and Bargeron, L.M., Jr.: Surgical treatment of straddling tricuspid valves. Circulation, *60*:655, 1979.)

CURRENT PRACTICE

Controversy still exists concerning the best approach to the patient with two good AV valves. For a patient with low pulmonary vascular resistance, a mildly dilated ventricle, no AV valve insufficiency, no subaortic stenosis, and resectable subpulmonary stenosis, the operative risks of septation and the Fontan-type operation are similar. The need for a valved external pulmonary conduit or AV valve replacement sigificantly increases the risk of septation. On the basis of morphology alone,[244,245] the Fontan procedure is applicable in many more patients than the septation operation. Improved operative risk following the Fontan–Kreutzer type operation, and the good late results make this our present operation of choice for patients in whom either operation could be applied. Palliative procedures are chosen to allow survival, alleviate symptoms, and preserve the anatomy and physiology for later Fontan repair.

In neonates presenting with cyanosis in spite of adequate ventilation and high inspired oxygen concentation, and in whom the diagnosis of cyanotic congenital heart disease is highly suspected, prostaglandin E_1 infusion is begun before transport to the cardiovascular center. Initial evaluation is by two-dimensional and Doppler echocardiography.

If echocardiography demonstrates pulmonary atresia or severe stenosis, catheterization and angiography are undertaken to define the distal pulmonary artery anatomy, arch anatomy, and pulmonary venous connection. If associated left AV valve stenosis or atresia is present and the atrial septum is relatively intact, a balloon atrial septostomy is attempted. A modified Blalock-Taussig shunt is placed within 48 hours of diagnosis, usually on the same side as the aortic arch. If pulmonary venous return is obstructed at the level of the atrial septum (with left AV valve stenosis/atresia) and this cannot be relieved by balloon septostomy, then surgical resection of the atrial septum is performed. If obstructed total anomalous venous return is present, this is repaired. As the patient grows, cyanosis usually progresses. A second shunt, either modified or classic Blalock-Taussig, may be required. Repeat cathe-

terization is required to document the status of the branch pulmonary arteries following shunting procedures.

If ventricular function, AV valve competency, and pulmonary vascular structures are acceptable, elective Fontan operation is planned between two and five years of age. Secure information concerning elective Fontan-type repair for younger children is not presently available but may in the future reduce the age for elective operation.

If moderate pulmonary stenosis is seen by echocardiography and adequate oxygen saturation is present on room air, catheterization may be safely postponed. Continuous-wave Doppler examination may be used to document pulmonary artery pressure when the ventricular pressure is known and the gradient is estimated. Later in infancy, elective catheterization and angiography are undertaken to confirm echocardiographic diagnoses and to evaluate details of systemic venous, pulmonary venous, and pulmonary arterial anatomy less securely evaluated by echocardiography. If the echocardiographic and Doppler data do not securely establish the presence of low pressure in the pulmonary artery, then catheterization should be planned earlier, within the first three months of life. If pulmonary artery flow and pressure require reduction, banding is considered.

If early evaluation reveals no pulmonary stenosis, the ventricular anatomy assumes a great importance. Catheterization is usually performed in the first three months of life. If there is no suggestion of subaortic stenosis and the anatomy seems unlikely to lead to stenosis, then pulmonary artery banding may be undertaken. Careful followup for any evidence of subaortic stenosis is necessary. Banding will more likely be a reasonable option when the dominant ventricle is of right or indeterminate morphology.

When there is a dominant left ventricle and the aorta arises from the nondominant chamber and the ventricular septal defect is huge, banding may be considered. If the ventricular septal defect is small or of moderate size, banding seems likely to result in progressive subaortic stenosis and other options must be considered. At present, inadequate data exist to make secure recommendations. However, we would presently perform a pulmonary-artery-to-aorta anastomosis and provide pulmonary blood flow by a modified Blalock-Taussig shunt. Alternatively, if two good AV valves are present, one might proceed with a two-stage approach to septation as reported by Ebert.[103] In an older patient, enlargement of a restrictive ventricular septal defect may be possible.

Patients with severe coarctation also require repair in the neonatal period. When coarctation is associated with severe subaortic stenosis, a modification of the Norwood operation for hypoplastic left heart may be applied.

We presently reserve septation as an option for older patients with optimal internal anatomy and moderate elevation of pulmonary artery resistance for whom Fontan repair is not advisable. If there is resectable pulmonary stenosis and if the ventricle does not appear enlarged on chest roentgenography, a Blalock-Taussig shunt may be placed to induce ventricular enlargement.[148] Septation with resection of subpulmonary stenosis is then undertaken six months to one year later. If AV valve replacement or a valved external pulmonary conduit is required, septation may be attempted (recognizing higher operative and late risk).

Many patients are not acceptable candidates for either septation or Fontan-type repairs. In older patients with cyanosis and pulmonary artery abnormalities that prevent a Fontan operation, the Glenn shunt must not be forgotten. When distal pulmonary arteries are preserved and venous anatomy is not too complex, but ventricular function is failing, cardiac transplantation may be considered.

Finally, these hearts might possibly be noticed on prenatal obstetrical ultrasound scanning. At present, a quite accurate prenatal anatomic diagnosis could be made with subsequent high-resolution scanning and Doppler echocardiography. Options are now limited to counseling and planning peripartum and postnatal management. However, as the technology for prenatal intervention improves, the opportunity to alter, prenatally, the severe associated left outflow obstruction may benefit some of these patients.

CHAPTER 75

Cardiac Malposition and Heterotaxy

Howard P Gutgesell

CARDIAC MALPOSITION

Terminology

Cardiac malposition has fascinated clinicians, pathologists, and embryologists for centuries. The abnormal location of the heart within the body is frequently associated with complex intracardiac anomalies and the absence, duplication, or abnormal location of the other viscera. Apart from their obvious challenge to the clinician, these conditions represent the ultimate test for any system of nomenclature and classification of congenital heart disease. Unfortunately, comprehending the literature that describes the cardiac malpositions is often more difficult than understanding the lesions. The following review of terminology gives the reader a basis on which to interpret the large, and sometimes confusing, body of literature pertaining to cardiac malposition and heterotaxy.

cardiac malposition: Location of the heart anywhere other than its usual position in the left hemithorax, or location of the heart in the left hemithorax when other organs are in an abnormal position such as situs inversus.

concordant, discordant: These terms commonly are applied to relations between atria and ventricles and between ventricles and great arteries. A right atrium connected to a right ventricle is concordant (normal), whereas a right atrium connected to a left ventricle is discordant. Thus, in situs solitus of the viscera and atria, the terms *L-loop ventricles* and *atrioventricular discordance* are essentially synonymous since they each describe a right atrium connected to a left ventricle and a left atrium connected to a right ventricle.

dextrocardia, levocardia, and mesocardia: These are general terms indicating the cardiac position only. They do not, in themselves, describe intracardiac anatomy. Dextrocardia denotes a heart in the right chest, levocardia a heart in the left chest, and mesocardia a midline heart.

d-loop; l-loop: These terms refer to the folding of the embryonic cardiac tube at about 23 days gestation. The loop normally bends toward the right (dextrally, d-loop). As a result, that portion of the primitive heart tube destined to become the right ventricle normally lies to the right of the anatomic left ventricle. If the cardiac tube bends to the left (l-loop), the future anatomic right ventricle lies to the left of the future anatomic left ventricle. A d-loop is normal in situs solitus and an l-loop is expected or "normal" in situs inversus.

heterotaxy: An abnormal arrangement of body organs that is different from the orderly arrangements of situs solitus or situs inversus. Typically, there is duplication or absence of normally unilateral structures (especially the spleen). Many authors have used the terms *situs ambiguous (ambiguus* if Latin is preferred) or *indeterminate situs* to describe this condition.[1–7]

inversion: Unfortunately, the term *inversion* has been used in two different ways to describe cardiac abnormalities. Several authors[18–21] have used this term to mean inverted relative to the usual relationship *within the body.* That is, a relationship in which the anatomic right ventricle lies to the left of the anatomic left ventricle is said to represent ventricular inversion. Others,[12] including Mullins in Chapter 73 of this text, use the term *ventricular inversion* to describe an abnormal relation of ventricles *to the atria,* irrespective of their position within the body (i.e., a discordant atrioventricular connection). Thus, the term *inversion* is ambig-

uous, and it should probably be replaced by less confusing terminology.

isomerism: The presence of paired, mirror-image sets of normally unilateral structures such as the lungs and atria. Left isomerism refers to the presence of two anatomic left lungs and two anatomic left atria, whereas right isomerism implies bilateral right lungs and atria. These terms are preferred by some[8] to polysplenia syndrome (for left isomerism) and asplenia syndrome (for right isomerism). (See discussion below.)

situs inversus: An arrangement of organs that is the mirror-image of normal (i.e., heart, stomach, and spleen on right; liver on left).

situs solitus: The usual or normal location of organs and vessels within the body (heart on left, liver on right, spleen on left, etc.).

transposition, transposition of the great arteries: Despite the frequency of this condition among patients with congenital heart disease, it has been difficult to formulate a universally accepted definition. Most definitions have been based upon one of the following concepts:

1. The interrelationships of the great arteries in space. Transposition has been defined as an anterior aorta and a posterior pulmonary artery.[9–12] Note that some investigators[13] use this definition literally, irrespective the ventricular origin of the great arteries. The term *malposition* has been used[14–16] to indicate an abnormal spatial relation between the aorta and pulmonary artery, without specifying their ventricular origins (thus, d or l malposition of the aorta).
2. The connections of the great arteries to the ventricles. Transposition has been defined as origin of the aorta from the right ventricle and origin of the pulmonary artery from the left ventricle (*trans* = across, *ponere* = to place). Thus, transposition is considered present when the great arteries are placed across the ventricular septum compared to normal.[5,6,14,16–18]
3. Physiology. Return of the systemic venous blood to the aorta and pulmonary venous blood to the pulmonary artery may be called transposition. Since this definition is not applicable to postmortem specimens, it is not used widely despite its obvious clinical importance. The term *complete transposition* also has been used to describe this form of physiology as distinguished from *corrected* transposition. The latter term has been applied to conditions such as situs solitus of the atria, atrioventricular discordance, and ventriculo-arterial discordance, in which systemic and pulmonary venous blood is directed appropriately to the pulmonary artery and aorta, respectively.

The nomenclature used to describe congenital abnormalities has evolved over several centuries. Until the 1960s and 70s, it was customary to describe cardiac malformations as discrete entities (e.g., "mitral atresia," "corrected transposition"). However, there are an almost infinite number of congenital malformations of the heart. Therefore, recent students of cardiac pathology have developed systematic classification systems designed to describe any cardiac malformation, however complex.[4–7,23] The segmental approach to the description of cardiac defects introduced by Van Praagh[3,21,24,25] forms the basis of virtually all current nomenclature schemes. Using this method, hearts are described according to three major segments and the connections between these segments:

1. visceroatrial situs (i.e., the location of the viscera and atria).
2. the ventricular anatomy, including the relationship of the ventricles to each other and their connections to the atria.
3. the conotruncus, which includes the locations of the infundibulum and great arteries.

The possible descriptions for each segment are outlined in Table 75–1. Note that although the situs may be "ambiguous" to the clinician, it is generally either left or right isomerism to the pathologist. Additionally, it is apparent that in visceroatrial situs solitus or inversus the terms *atrioventricular concordance* or *discordance* suffice to describe the atrioventricular relationship. In left or right atrial isomerism, however, these terms are not applicable and a designation of the type of ventricular looping is required. Finally, note that the terms are totally independent of the terms *dextrocardia, mesocardia,* and *levocardia,* which simply designate the location of the heart within the body.

Implicit in the descriptions of hearts by this method is the understanding that the bronchial tree, lungs, atria, and ventricles are named on the basis of their *anatomic* features rather than their *location* within the body. This concept, assumed by pediatric cardiologists and pathologists, is often confusing to others. It appears to have originated with Lev's study of cardiac malposition in 1954,[26] and it is hard to improve upon his explanation:

> A chamber cannot be designated according to the vessel of entry or exit, nor according to the valve of entry or exit, since these are variables in congenital heart disease. Likewise, a chamber cannot be designated according to its function since this is also a variable. The only sound method available is to designate a chamber according to its morphology.

Fortunately, all of the modern classification systems agree on this point. The pertinent anatomic features can be summarized as follows:

1. A right lung typically has three lobes and contains an eparterial bronchus that passes over the right pulmonary artery. A left lung has two lobes and does not contain an eparterial bronchus. The undivided left main stem bronchus is typically at least twice as long as the undivided right mainstem bronchus.[27,28] The situs of the lungs can be determined ra-

Visceroatrial situs
Solitus
Inversus
Heterotaxy (ambiguous, indeterminate)
Right isomerism
Left isomerism
Atrioventricular relationship
Concordant (d-loop ventricles in atrial situs solitus, l-loop ventricles in situs inversus)
Discordant (l-loop ventricles in atrial situs solitus, d-loop ventricles in situs inversus)
Ambiguous
Left or right atrial isomerism
Primitive ventricle
Great arteries
Normally related
Transposed
Double outlet
Single arterial trunk

diographically by using overpenetrated chest roentgenograms or tomography to delineate bronchial anatomy: the left lungs having long unbranched mainstem bronchi.[1,27–29]

2. An anatomic right atrium contains a crista terminalis and the limbus of the fossa ovalis. The appendage is broadbased and contains pectinate muscles. A left atrium lacks a crista terminalis and generally has a narrow-based appendage, which lacks pectinate muscles. The details of atrial anatomy are somewhat difficult to depict by current imaging techniques. Therefore, atrial anatomy usually is inferred from bronchial anatomy because of the very high degree of concordance between the "sidedness" of the bronchi and that of the atria.
3. The right ventricle is characterized by coarse trabeculations, a muscular conus separating the semilunar valve from the atrioventricular valve, and a tricuspid valve with some chordae that attach to the ventricular septum. A left ventricle has fine trabeculations, no conus (i.e., there is normally aortic–mitral fibrous continuity), and a mitral valve that attaches to two papillary muscles (and not to the septum).

Fortunately, the aorta and pulmonary artery have unique names that are unrelated to their usual location within the body.

Dextrocardia

Historical Aspects

The first reported cases of dextrocardia in humans appear to be those of Fabricius in 1606 and Servius in 1643.[30] The first classification system of dextrocardia was developed in 1749 by Senac,[31] who divided right-sided hearts into congenital and acquired forms. Numerous case reports appeared in the nineteenth century, and by the early twentieth century the literature contained several detailed classification systems.[32–35] Lichtman's review in 1931[36] contains no fewer than 370 references.

The clinical recognition and evaluation of dextrocardia was facilitated greatly by the development of roentgenography and electrocardiography. By 1915, both of these techniques had been applied to patients with dextrocardia.[37] Diagnostic accuracy has improved progressively as angiocardiography,[38–46] echocardiography,[47–51] and computed tomography[52,53] have been used to study patients with dextrocardia.

Incidence, Genetics, and Etiology

The incidence of situs inversus has been estimated as between 1/2500 and 1/20,000 living persons,[54–57] with 1/7000–1/8000 the most common estimate from mass radiographic surveys of adults.[56,57] Dextrocardia with situs solitus (isolated dextrocardia) is thought to be less common, with incidence estimates of 1/7500,[54] 1/17,500,[58] and 1/29,000.[57] In contrast, among patients referred to pediatric cardiology clinics, those with isolated dextrocardia are seen more commonly than those with situs inversus. This is, no doubt, related to the much higher incidence of intracardiac abnormalities in the former group. Campbell and Deuchar[59] identified 29 patients with dextrocardia in a group of 1130 patients with congenital heart disease (2%). Ten of these had situs inversus, 16 had situs solitus, and 3 had situs ambiguous.

In the autopsy series tabulated by Van Praagh,[21] there were 136 cases of dextrocardia: 66 had situs solitus, 24 situs inversus, and 46 situs ambiguous. Among 43 autopsied cases of dextrocardia, Stanger et al. found situs solitus in 12, situs inversus in 11, and asplenia/polysplenia in 20. Thus, although isolated dextrocardia is rare in mass radiographic surveys, it is the most common form of dextrocardia in young patients dying from congenital heart disease.

The genetic basis of dextrocardia in humans is unknown. Cockayne[60] believed that situs inversus was an autosomal recessive trait, citing the familial incidence and distribution within families, occurrence in 5 of 6 pairs of monozygotic twins, and a high incidence of first cousin marriages. Others have questioned this hypothesis,[57,61] largely because of the low incidence in siblings of propositi (1/51 to 1/91). More than one genetic mechanism may be operant: Workany[62] notes that although situs inversus behaves like a recessive trait in many families, in others it appears to be autosomal-dominant. Conversely, the relatively low incidence of concordance in monozygotic twins in his series (6 of 12 reported pairs) suggested that nongenetic factors play a role in the expression of situs inversus.

Little is known about the etiology of genetics of dextrocardia with situs solitus. Lowe and McKeown[57] found neither familial recurrences nor parental consanguity in their cases. Presumably, the recurrence risk is the same as that for congenital heart disease in general, 2 to 4%.[63]

The genetics of situs inversus in mice has been reviewed by Layton.[64–66] Situs inversus is inherited as an autosomal recessive trait. The normal allele at the *iv* locus (+/*iv*) causes situs solitus (normal laterality). Fifty % of mice homozygous for the gene *iv* (i.e., *iv*/*iv*) have situs inversus, and 28% have heterotaxia of major veins and abdominal organs. Major cardiac abnormalities occur in a high percentage of newborn mice with the iv/iv genotype. Layton hypothesized that the normal allele (+/*iv*) specifies situs solitus. In the homozygous state, this control is absent and situs is determined in a totally random manner. Thus, with the iv/iv genotype, situs solitus and situs inversus occur with equal frequency.

Embryology

The primitive cardiac loop normally bends toward the right at the eight somite stage (approximately 22 to 23 days gestation).[67,68] During the next 10 to 12 days, while cardiac and great vessel septation is occurring, the apex of the heart gradually migrates from the right side of the thorax to its normal location in the left hemithorax. In situs solitus, dextrocardia has been explained as lack of this normal leftward migration of the cardiac mass.[69–71] De la Cruz, et al.[70,71] have suggested a similar left-to-right migration of the l-loop ventricles normally present in situs inversus. Extending this reasoning, they have attempted to explain the high incidence of atrioventricular discordance (l-loop ventricles) in individuals with situs solitus and dextrocardia as a consequence of the natural tendency of an l-loop heart to migrate into the right hemithorax.

Nomenclature and Classification

A variety of terms have been used to describe hearts in the right side of the chest, including dextroposition, dextroversion, dextrorotation, and isolated, genuine, mixed, pivotal, true, and mirror-image dextrocardia. Since these terms are difficult to remember and have been interpreted differently by several authors, it is preferable to avoid their use altogether. However, since some are

used widely, a brief description of the most common terminology is necessary for interpretation of the literature. The terms *dextroversion,*[32,39,40,72] *dextrorotation,*[42] and *pivotal dextrocardia*[26,40] generally are used to describe dextrocardia with situs solitus. The heart often appears as if the apex simply has been swung from the left side of the chest to the right. Isolated dextrocardia[36] has a similar connotation, implying that the other organs are in their normal location with respect to the body and that dextrocardia is an isolated finding. Dextroposition implies that the heart has been shifted rightward by external causes.[40,74] Mixed dextrocardia is a term used to indicate dextrocardia with atrioventricular discordance.[40,68,73] Mirror-image dextrocardia generally is applied to more-or-less normal hearts in subjects with situs inversus.

It is reasonable to consider separately those cases of dextrocardia that are due to displacement of the heart into the right hemithorax by external causes—pneumothorax, diaphragmatic hernia, or hypoplasia of the right lung—a condition sometimes referred to as secondary dextrocardia. The remaining hearts must be described in a segmental manner, as outlined above. The location of the other viscera is key since the presence of situs solitus, situs inversus, or heterotaxy have major implications in terms of the likelihood and type of intracardiac abnormalities. Thus, the simplest classification system is one that separates cases of secondary dextrocardia, then divides the remainder according to visceral situs (Table 75–2).

Clinical Evaluation

Although dextrocardia can be diagnosed by physical examination, most likely it is detected by chest roentgenography. The clinical presentation may be that of a newborn with cyanosis, respiratory distress, or a heart murmur. Occasionally, dextrocardia is detected on a chest roentgenogram performed as a screening test or evaluation for other medical disorders.[54,56,57] The incidence of congenital heart disease in secondary dextrocardia is not established. When dextrocardia is due to a simple mechanical factor such as pneumothorax, the incidence of heart disease is probably the same as that in the general population. Cases associated with other birth defects such as diaphragmatic hernia, however, may have a greater likelihood of intracardiac abnormalities. The incidence of congenital heart disease in primary dextrocardia varies from under 10% in situs inversus to over 90% in situs solitus (see below). In cases of secondary dextrocardia, the chest roentgenogram may be the only necessary diagnostic test. In the absence of such an obvious cause, the initial step in evaluation of dextrocardia is to determine the situs of the other viscera. Frequently, the chest roentgenogram is useful in illustrating the location of the liver and stomach. The situs of the lungs may be inferred from chest films.[1,27–29] Although somewhat overshadowed by modern imaging techniques, the electrocardiogram is often helpful in evaluation of dextrocardia: a "P" vector directed leftward and inferiorly suggests situs solitus of the atria, whereas a rightward "P" axis suggests situs inversus (Fig. 75–1). Nonsinus pacemakers are probably responsible for most exceptions to the rule.[75,76]

Table 75–2. Simplified Classification of Right-Sided Hearts

Primary
Situs inversus
Situs solitus
Heterotaxy
Secondary (pleural, chest wall, or pulmonary causes)

Many of the details of visceral situs and intracardiac anatomy can be determined by echocardiography.[47–50,77–81] A comprehensive examination should include identification of the abdominal viscera, systemic venous connections to the heart, the atrioventricular connection(s), ventricular anatomy, ventriculo–arterial connections, and the anatomy of the aortic arch and pulmonary arteries. Additionally, the presence of septal defects, valvular stenosis or insufficiency, and pulmonary venous connections may be determined. Additional hemodynamic and anatomic data may be obtained by cardiac catheterization and angiocardiography.[38–46]

Associated Cardiac Abnormalities

Situs Solitus. Dextrocardia in the presence of situs solitus is frequently, but not invariably associated with major intracardiac abnormalities. The literature is somewhat difficult to interpret, since dextrocardia with situs solitus has been called dextrorotation,[42] dextroversion,[32,39,40,82] isolated dextrocardia,[36] type II dextrocardia,[40] and type III dextrocardia.[35] Most angiocardiographic and autopsy studies have revealed a very high incidence of intracardiac anomalies.[18,21,32,40–46,73,83–86] The most common findings are summarized in Table 75–3. Atrioventricular discordance (l-loop ventricles) is a frequent finding, present in nearly half of cases. Over one-fifth of cases have single ventricle and the majority of the remainder have ventricular septal defect. Ventriculo–arterial discordance (transposition) is the most common relation of the great arteries. About half of cases described have atrioventricular discordance and ventriculo–arterial discordance, and thus the physiology of "corrected" transposition. Normally related great arteries are present in about 8%. Pulmonary stenosis or atresia is common (60%) and right aortic arch uncommon (4%).

Although the incidence of congenital heart disease is said to approach 100% among patients with situs solitus and dextrocardia,[53] this estimate, based largely on autopsy and angiocardiographic data, is probably too high. Scattered cases of situs solitus, dextrocardia, and normal intracardiac anatomy are reported in the literature[18,21,39,46]; presumably, many more are undetected in the absence of symptoms or cardiac murmurs. Some of these may be secondary to hypoplasia of the right lung (Fig. 75–2).

Scimitar syndrome: The scimitar syndrome is an uncommon but

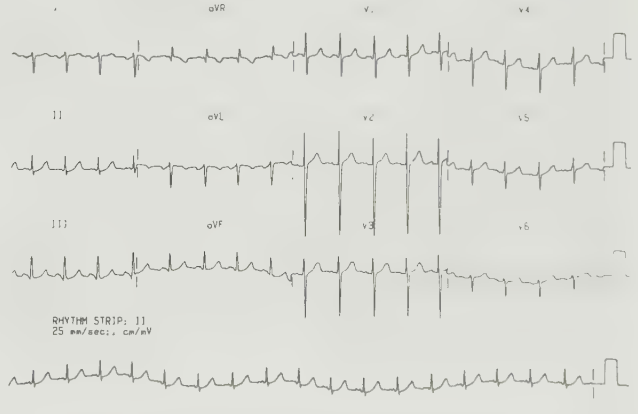

Fig. 75–1. Electrocardiogram from patient with dextrocardia and situs inversus. Note the negative waves in lead I and the progressively decreasing voltage in left chest leads.

Table 75–3. Intracardiac Abnormalities in Patients with Right-Sided Hearts Studied by Angiocardiography or Autopsy

	Dextrocardia with Situs Solitus	*Dextrocardia with Situs Inversus*
AV discordance	50%	25%
Single ventricle	25%	Uncommon
VSD	60%	60%
"Corrected" TGA	50%	20%
"Complete" TGA	10%	30%
DORV	10%	30%
NRGA	40%	40%
PS/PA	60%	50%
Right aortic arch	5%	80%

Note: Percentages listed are approximations based on 188 cases of dextrocardia with situs solitus[18,21,40,45,46,73,84] and 89 cases of dextrocardia with situs inversus.[18,21,40,46,84] Differences in terminology preclude a precise tabulation. Total for great artery configurations exceeds 100% because some reports did not consider TGA and DORV mutually exclusive diagnoses.

Key: AV = atrioventricular; DORV = double outlet right ventricle; NRGA = normally related great arteries; PS/PA = pulmonary stenosis or pulmonary atresia; and TGA = transposition of great arteries.

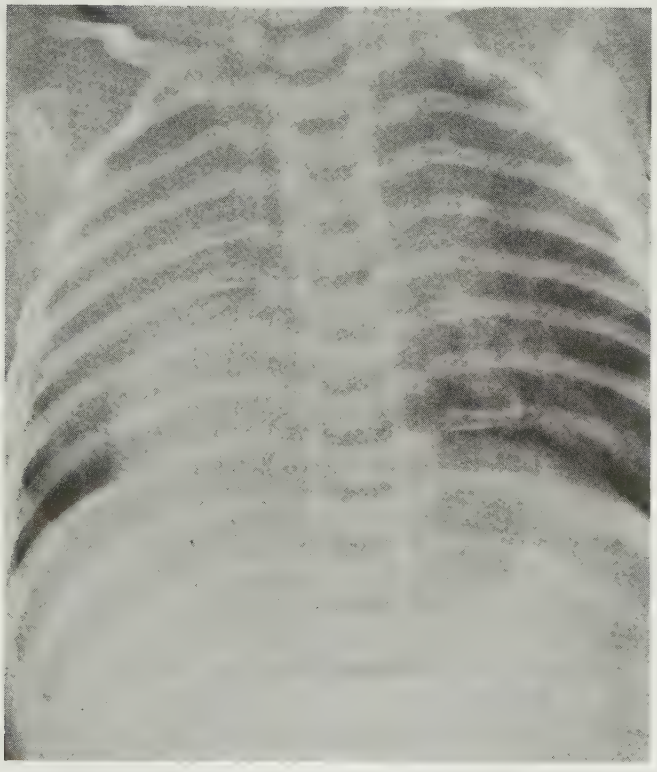

Fig. 75–2. Dextrocardia in a neonate with mild respiratory distress. Patient had situs solitus and normal intracardiac anatomy. Density in right hemithorax suggests atelectasis and/or hypoplasia of right lung.

well-described constellation of cardiopulmonary anomalies consisting of dextrocardia, situs solitus of the atria and viscera, hypoplasia of the right lung, anomalous systemic arterial blood supply to the right lung and anomalous pulmonary venous connection of the right lung to the inferior vena cava. The anomalous pulmonary vein is often visible on the chest roentgenogram as a curvilinear shadow in the right lung and resembles a Turkish sword or "scimitar" (Fig. 75–3).

There appear to be two relatively distinct clinical patterns of the scimitar syndrome: 1) infants with cyanosis, respiratory distress, and failure to thrive often with pulmonary hypertension and complex intracardiac defects[87–89]; and 2) a group of older children and adults who present with a heart murmur, recurrent pulmonary infection, or only an abnormal chest roentgenogram[90] (see Fig. 75–3). The latter group has a very favorable prognosis with or without surgery (right pneumonectomy). Approximately 40% of cases of scimitar syndrome diagnosed in childhood have associated intracardiac anomalies.[91–94]

Situs Inversus. The incidence of congenital heart disease in subjects with dextrocardia and situs inversus is much less than for dextrocardia and situs solitus, but precise determination is not available. Korth and Schmidt[83] reviewed 1000 cases of mirror-image dextrocardia with situs inversus and found congenital heart disease in only one (an incidence lower than that usually cited for the incidence of congenital heart disease in the general population).[63]

The consensus of opinion regarding the individual with situs inversus aptly was summarized by Cleveland[30] in 1926:

> He does not seem to be left handed more than his fellows. He is apt to live his life unmarked by any peculiarity and die of the same diseases that carry off the rest of mankind . . . The European case reports usually end with the observation that the individual was quite fit for military duty.

This picture of situs inversus is quite different from that depicted for patients with situs inversus who are referred to pediatric cardiology clinics[40–46,49,53,85] or described in autopsy series.[18,21,24–26] These studies all report a very high incidence of congenital heart disease obviously reflecting the reason for referral.

The types of cardiac abnormality found in dextrocardia with situs inversus are summarized in Table 75–3, and an example is illustrated in Figure 75–4. Atrioventricular discordance and transposition complexes are common, but less frequent than in dextrocardia with situs solitus. Physiologically complete forms of transposition are more common than so-called corrected forms. Double-outlet right ventricle, pulmonary stenosis or atresia, and ventricular septal defect are present in one-third to two-thirds of reported cases. The aortic arch is usually right-sided.

Although most patients with situs inversus have a normal heart, they are at greater risk for pulmonary diseases than the general population. The most notable of these is the so-called Kartagener syndrome. In 1933, Kartagener described four patients with situs inversus, chronic sinusitis, nasal polyposis, and bronchiectasis.[95] Subsequent studies by Kartagener[96] and others[55,97,98] suggested that the incidence of bronchiectasis among patients with situs inversus (15 to 25%) was higher than expected by chance. The ultrastructural basis for the respiratory disease and the male infertility in this syndrome subsequently was shown to be due to an abnormality of the dynein arms on the microtubules of the cilia and spermat-

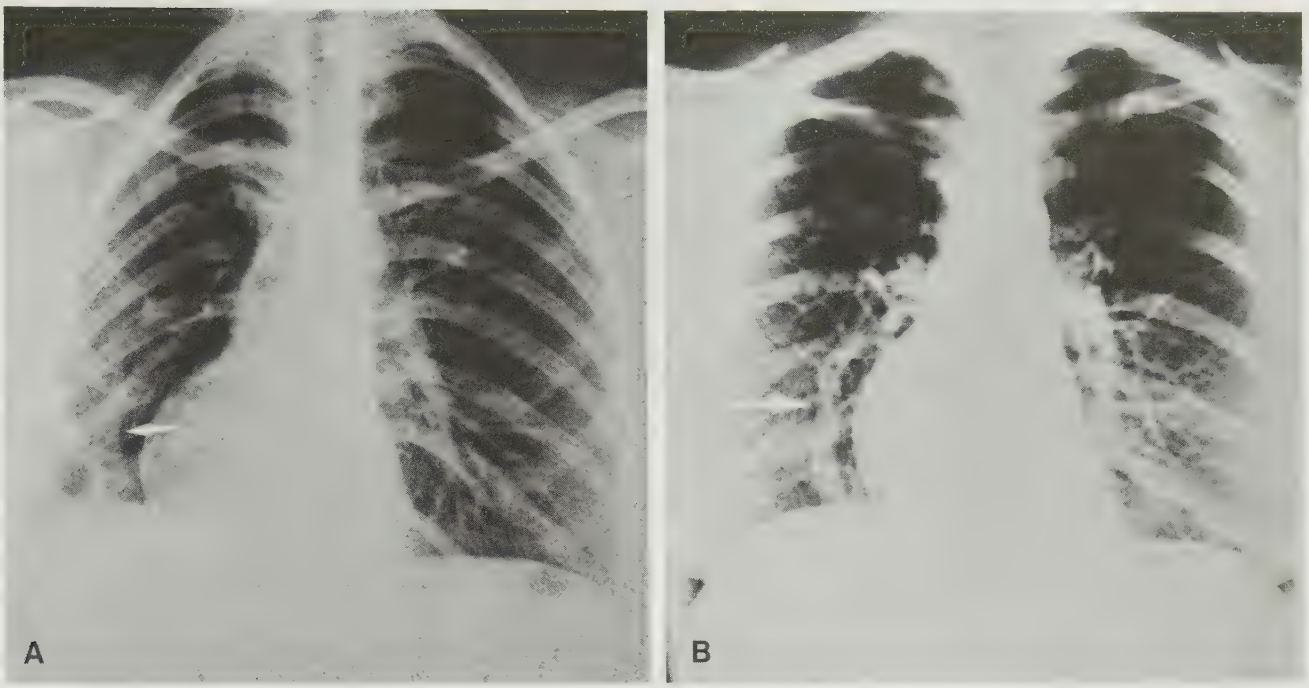

Fig. 75–3. Asymptomatic adults with dextrocardia and scimitar syndrome (A and B). Right pulmonary vein produces sword-shaped shadow (arrows) as it runs inferiorly toward diaphragm (especially well seen on the high-contrast film [B]). (Courtesy Drs. Peter Armstrong (A) and Paul Dee (B).)

ozoa, with resultant immotility of these structures and decreased mucociliary transport.[99–102]

Levocardia

Historic Aspects

Van Praagh[21] cites the reports of Martin,[103] and Breschet[104] as the first descriptions of isolated levocardia. The condition is quite rare and cases of isolated levocardia (in its simplest form, levocardia with situs inversus) often are included with descriptions of levocardia occurring in the asplenia/polysplenia syndromes.

Associated Cardiac Disease

Levocardia occurring in the presence of situs inversus or heterotaxy is almost invariably associated with major intracardiac anomalies[59,21,86,105–110] (Fig. 75–5). Of 65 autopsy cases reviewed by Van Praagh,[21] 9 were associated with situs inversus, and the remaining 56 had situs ambiguous. All 9 of the cases associated with situs inversus had D-ventricular loops and D-malposition of the aorta (two with double-outlet right ventricle). Thus, the physiology presumably resembled that of corrected transposition. Associated lesions included atrioventricular canal (6/9), total anomalous pulmonary venous connection (4/9), and pulmonary stenosis or atresia (8/9).

Thus, when the heart is left-sided but other viscera are not in their usual location: 1) the likelihood of intracardiac abnormalities is very high (close to 100%) and 2) the likelihood of either asplenia of polysplenia is high (about 80%).[25]

Mesocardia

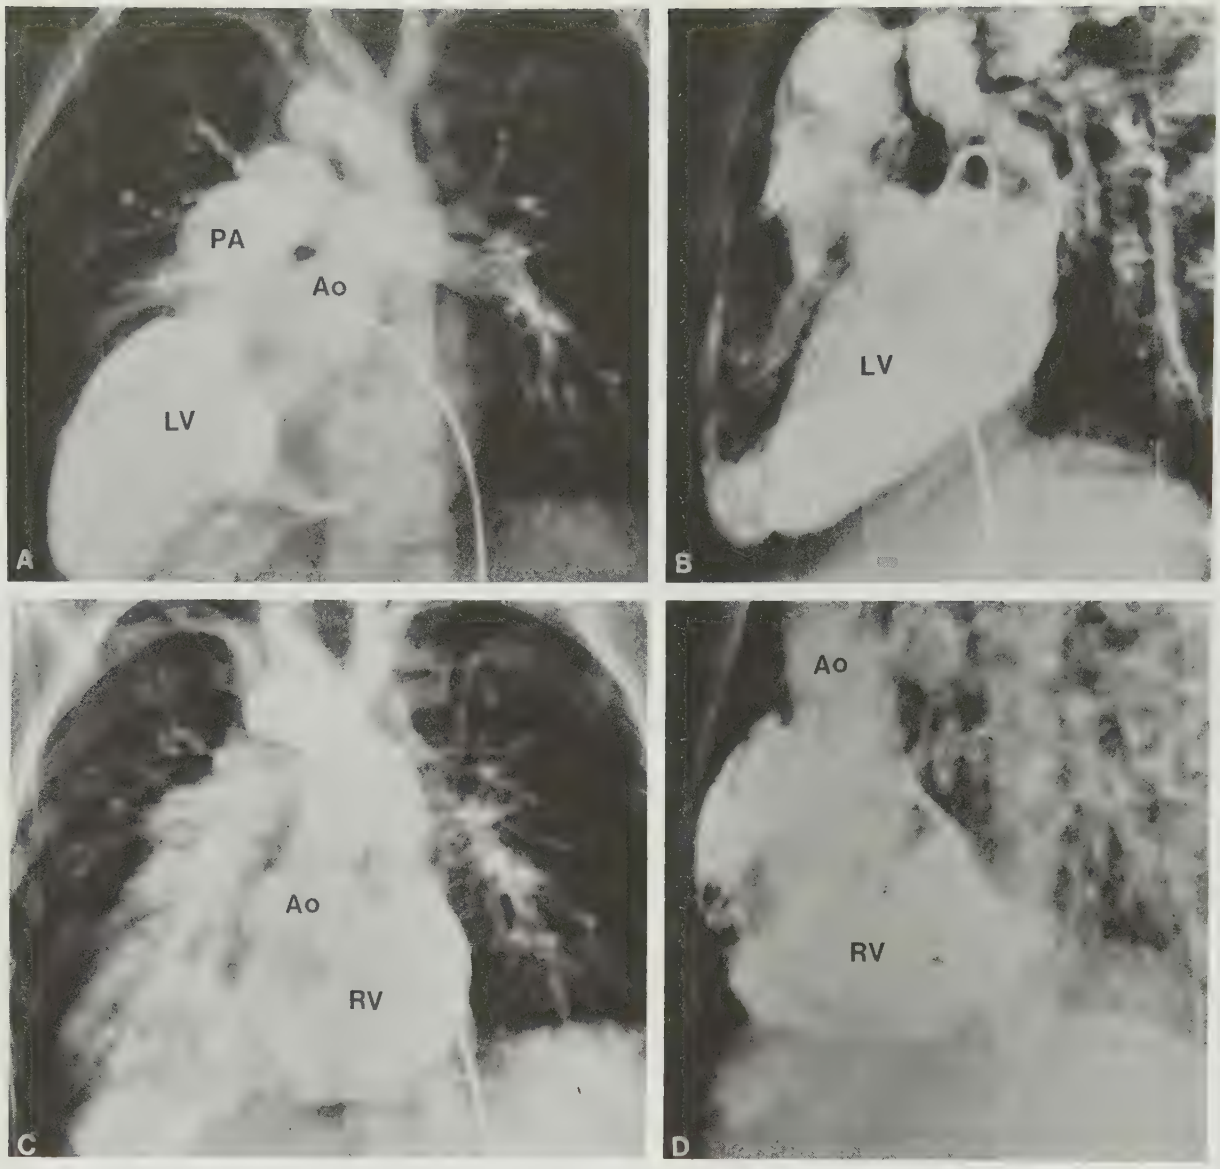
Mesocardia, defined as a midline heart that is in neither the left nor the right hemithorax, is either very rare or quite common, depending on the rigidity of the definition and the perspective of the beholder. Van Praagh[21] found mesocardia to be quite rare, occurring only in 0.2% of his *autopsied cases of congenital heart disease*. He analyzed 17 cases (4 of his own and 13 described by Lev[102]). Situs solitus was present in 12, situs inversus in 2, and situs ambiguous in 3. Normally related great arteries were found in 5 of these cases, corrected transposition in 3, and complete transposition in 2. Shaher[86] described five patients with mesocardia, all with situs solitus. Transposition was present in 2, patent ductus arteriosus in 2, ventricular septal defect in 1, and anomalous coronary artery in 1.

Clinicians viewing large numbers of chest roentgenograms have a somewhat different perspective. Many tall, slender adolescents and adults have an almost vertical heart, which might be termed *mesocardia*. As a result, some authors have suggested that mesocardia itself is of little or no consequence.[112,113] Thus, the setting in which it occurs is a much more important determinant of the likelihood of intracardiac abnormalities than the fact that the heart is in the midline; a cyanotic newborn with a murmur and a midline heart is quite likely to have serious heart disease whereas in an asymptomatic child with no murmur, a midline heart is probably of no concern (Fig. 75–6).

Summary

The following generalizations apply to hearts in abnormal locations with the thorax:

1. Dextrocardia with situs solitus (isolated dextrocardia) is almost always associated with intracardiac abnormalities, whereas atrioventricular discordance occurs with transposition of the great arteries the most common. The scimitar syndrome should be considered even in the absence of obvious intracardiac abnormalities.



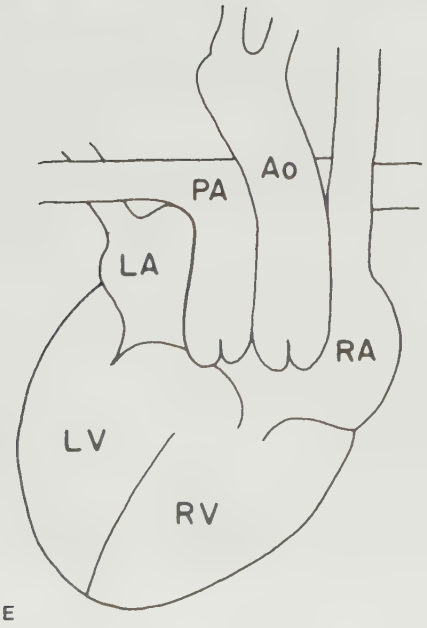


Fig. 75–4. Dextrocardia with situs inversus. From roentgenograms of the abdomen and from the course of the venous catheter, there is situs inversus of the viscera and atria. The right-sided ventricle has the morphology of a ''left'' ventricle (A and B) and the left-sided ventricle resembles a ''right'' ventricle (C and D). The great arteries are side by side, aorta to the left, and both arise from the anatomic right ventricle. As shown in (E), the anatomy may be summarized as dextrocardia, situs inversus of viscera and atria, atrioventricular concordance, and double outlet right ventricle (L-malposition of the aorta).

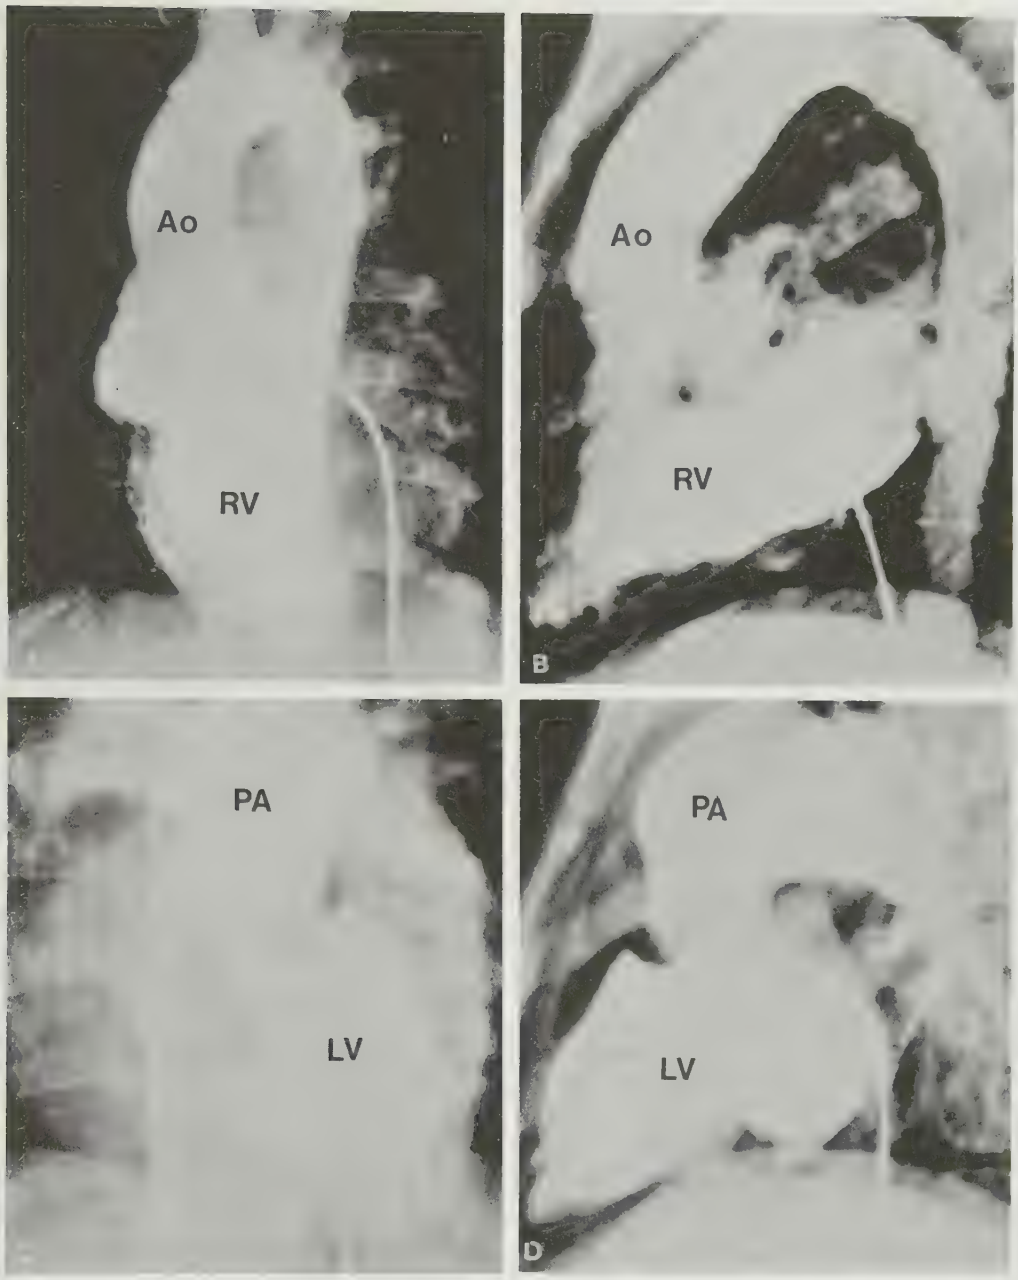

Fig. 75–5. Levocardia with situs inversus. Roentgenograms of the abdomen and the course of the venous catheter show situs inversus of the viscera and atria. The right-sided ventricle (A and B) has the morphology of a right ventricle and gives rise to the aorta. The left-sided ventricle (C and D) has left ventricular morphology and gives rise to the pulmonary artery.

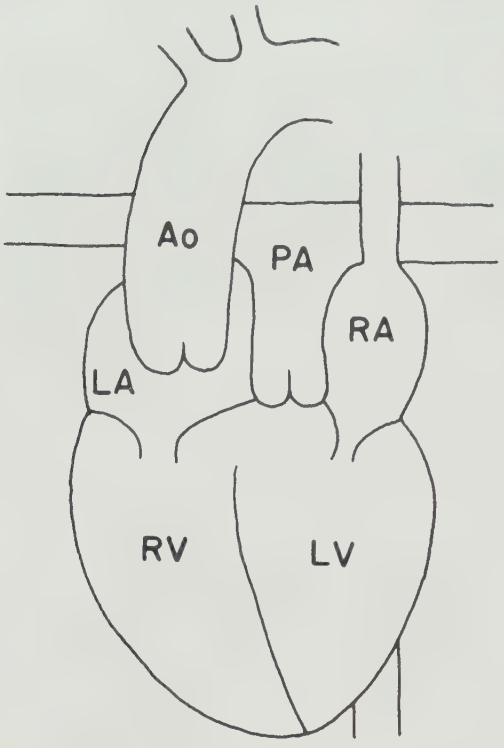
2. In dextrocardia with situs inversus, the incidence of congenital heart disease is probably the same as in the general population, but it is much higher among those patients referred to cardiology clinics. The Kartagener syndrome is present in 15 to 25% of patients with situs inversus.
3. Isolated levocardia is almost invariably associated with major intracardiac abnormalities.
4. Approximately one-third of patients with dextrocardia and at least two-thirds of those with isolated levocardia have either asplenia or polysplenia.

HETEROTAXY

Definition

Unlike the orderly and predictable arrangements of the organs and blood vessels in situs solitus and situs inversus, those of the visceral heterotaxy syndromes appear random and disorderly. Thus, these conditions often are referred to as situs ambiguous or situs indeterminate. Within this group of conditions are two predominant patterns: those associated with asplenia and those associated with polysplenia. Individuals with asplenia frequently



E

Fig. 75–5 (cont.) As summarized in (E), there is levocardia, situs inversus of viscera and atria, atrioventricular discordance (d-loop), and transposition of the great arteries (complete transposition with d-malposition of the aorta).

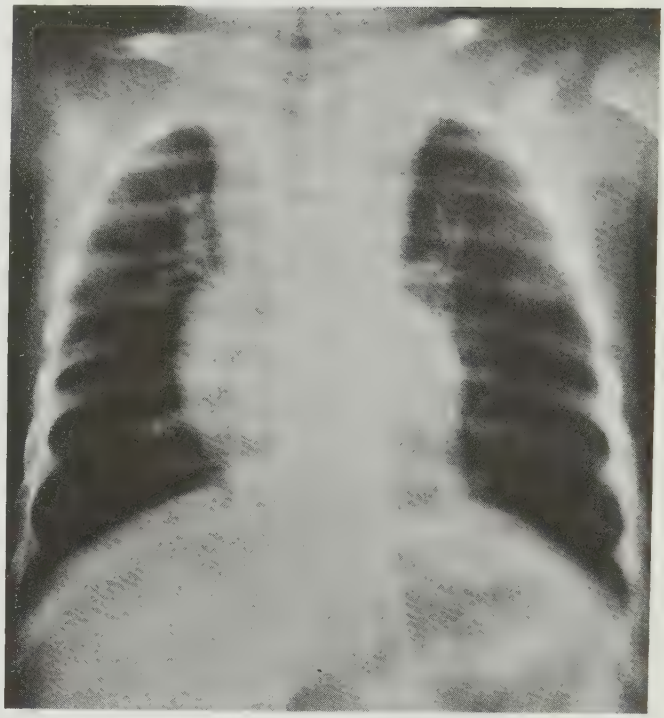


Fig. 75–6. Chest roentgenogram in an asymptomatic 2-month-old infant with a midline heart (''mesocardia''). Patient has situs solitus and normal intracardiac anatomy, illustrating that the presence of mesocardia itself does not necessarily indicate serious underlying congenital heart disease.

have internal viscera resembling bilateral right-sidedness whereas those with polysplenia frequently appear to have bilateral left-sidedness. Macartney et al.[8] have argued that these conditions should be termed right or left isomerism since the situs is not truly ambiguous and the presence or absence of the spleen is an inconstant variable. Freedom[104] concluded that these conditions represented abnormal persistence of normally symmetric embryonic structures rather than bilateral left- or right-sidedness. Nonetheless, the terms *asplenia syndrome* and *polysplenia syndrome* are used widely and provide a simple memory aid for understanding the conditions. (It is easy to remember that an individual with two right sides would have no spleen and one with two left sides might have several spleens.)

The two conditions thus are discussed below as separate syndromes (not specific malformations or diseases) of commonly occurring constellations of visceral and cardiac abnormalities.

Historical Aspects

Although congenital absence of the spleen has been recognized for over 200 years,[115] it was not until the 1950s and the publication of several large series of autopsied cases of asplenia[115–117] that there was an appreciation of the almost-invariable presence of a specific set of cardiovascular abnormalities in patients born without a spleen. As a result of his exhaustive treatise on the subject,[117] Ivemark's name has been associated with the constellation of cardiac malformations associated with asplenia: ''the Ivemark syndrome.'' Ivemark called attention to the appearance of bilateral right-sidedness in asplenia and bilateral left-sidedness in polysplenia, findings subsequently reiterated by others.[2,118–121]

Incidence, Etiology, and Genetics

The heterotaxy syndromes, while not common in the general population, are by no means rare, especially in tertiary care centers with neonatal intensive care units. The asplenia/polysplenia syndrome is present in 3% of neonates with structural heart disease[122] and in 30% of patients dying with cardiac malposition.[21]

The etiology of the heterotaxy syndromes is undetermined. As just described, Layton's hypothesis[64–66] of a lack of normal genetic control leading to random organization of viscera is an appealing theory that would explain many aspects of cardiac malposition and heterotaxy. Other factors that have been proposed as causes of asplenia syndrome include: 1) vascular disturbances resulting in agenesis of the spleen[115]; 2) failure of the splenic artery to reach the developing spleen[123]; 3) abnormal embryonic body curvature.[124]

The familial clustering of cases of situs inversus, asplenia, and polysplenia suggests a common genetic basis.[125–126] In reviewing the genetics of these conditions, Niikawa et al.[125] found reports of eight families with two or three sibs with asplenia; four sibships with two to four sibs with polysplenia; two brothers, one with situs inversus and one with asplenia syndrome, born to consanguineous parents; and two sibships where one sib had asplenia and one had polysplenia. Nukawa et al.[125] described a family in which a father with situs inversus totalis had one child with asplenia syndrome and another with polysplenia syndrome. Schidlow et al.[127] have described a sibship in which one side had Kar-

tagener syndrome and another polysplenia syndrome; both had abnormal respiratory cilia.

Embryology

Heterotaxy obviously is not a specific disease but a constellation of cardiac, vascular, and visceral abnormalities. The embryology of many of the specific cardiovascular abnormalities is discussed in the chapters dealing with these malformations.

The major events in normal cardiac development that appear to be arrested or lacking in the hearts of patients with the heterotaxy syndromes occur largely during the fifth week of gestation.[67,68,128] During this week, the cardiac tube (already bent toward the right or left) undergoes septation. The growth of the endocardial cushions, septation of the conotruncus, lobation of the lungs, and rotation of the gut begin between the 28th and 35th gestational day. The connection between the roof of the left atrium and the pulmonary venous plexus is established by 30 to 32 days.[129] The spleen, which arises from the left side of the dorsal mesogastrium, is present histologically in 7.5- to 8-mm embryos (about 32 days) and is well demarcated in 13.5-mm embryos (35 to 36 days).

The hearts of many patients with either asplenia or polysplenia bear a rather striking resemblance to the heart of a normal embryo of about 35 weeks gestation. This has led to the suggestion that the asplenia syndrome results from a teratogenic insult in the fifth week of gestation,[115,131] although a more fundamental defect with a genetic basis seems more plausible.

Asplenia Syndrome

Clinical Features

The usual presentation is in a cyanotic male newborn, often with respiratory distress. The first and second heart sounds are single (and, since dextrocardia is common, the heart sounds may be heard better over the right hemithorax). There may be an ejection systolic murmur, a continuous murmur, or no murmur. A midline liver often is identifiable by palpation.

Clues to the presence of the asplenia syndrome are often present on the chest roentgenogram[132,133] (Figs. 75–7 and 75–8), and this condition should be considered when the cardiac position is discordant with that of the stomach and liver, especially if pulmonary vascular markings are very diminished (due to pulmonary atresia) or there is pulmonary edema (obstructed pulmonary veins) (see Fig. 75–8).

The electrocardiogram is generally abnormal, but the findings are not specific for asplenia. The P wave axis may be either leftward and inferior (normal) or rightward and inferior,[134,135] or both, because of the frequency of bilateral sinus nodes.[121,136] Two atrioventricular nodes may be present.[136] Congenital complete AV block occasionally is present[137] and was diagnosed prenatally in the patient depicted in Figure 75–9. The frontal plane QRS axis and morphology reflect the cardiac position and intracardiac anatomy; the frontal plane QRS axis tends to be superior in the presence of two ventricles and inferior when there is a single ventricle.[138] The precordial leads may suggest left, right, or biventricular hypertrophy.[138]

The details of intracardiac anatomy and systemic and pulmonary venous connections can be established by two-dimensional echocardiography.[78] A transverse abdominal scan in a plane just inferior to the diaphragm is a useful starting point (see Fig. 75–8C). This

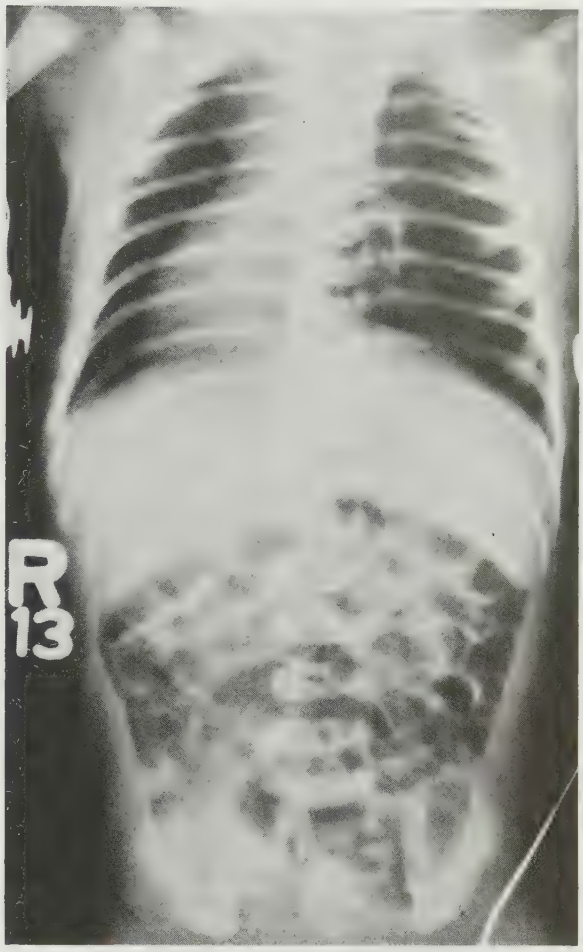

Fig. 75–7. One-day-old infant with dextrocardia and heterotaxy. Note stomach on left and large midline liver. Patient had atrioventricular canal, transposition of the great arteries, and pulmonary atresia. Autopsy demonstrated asplenia.

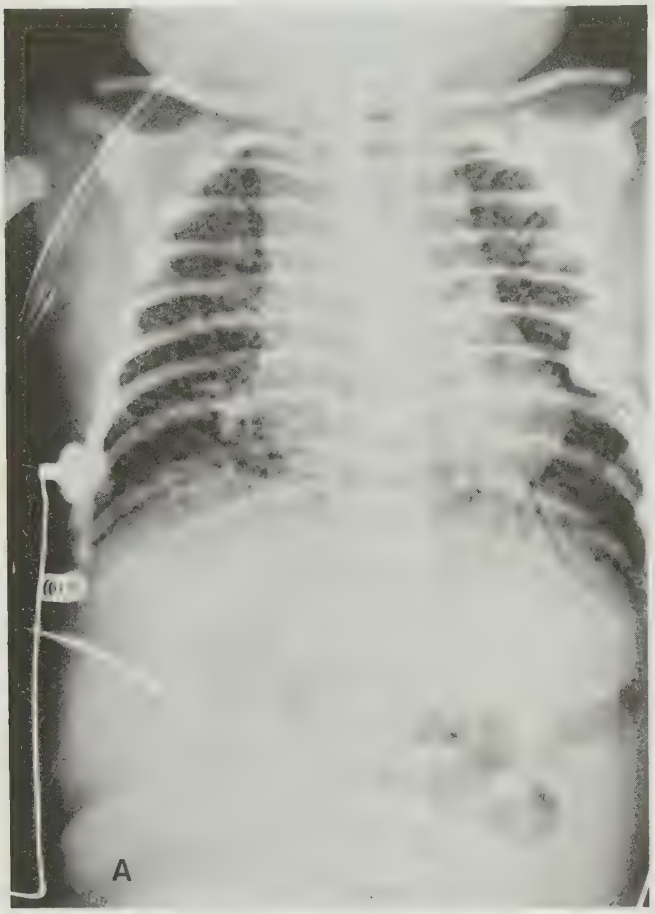
establishes the location of the liver, the inferior vena cava (if present) and the abdominal aorta. A subcostal four-chamber view will illustrate the location of the heart within the chest, the location of the cardiac apex, and the details of intracardiac anatomy (see Fig. 75–8). Because of the high incidence of total anomalous pulmonary venous connection, particular care is needed to determine the route of pulmonary venous return (see Fig. 75–8D).

Additional anatomic and physiologic information, if required, can be obtained from cardiac catheterization and angiocardiography (Fig. 75–10). These studies are particularly useful to document the presence of pulmonary venous obstruction, although catheterization of the pulmonary arteries may be difficult, or impossible, because of the presence of pulmonary stenosis or atresia.

Documentation of the absence of the spleen is more difficult than the confirmation of its presence. The presence of Howell-Jolly bodies in the red blood cells in a peripheral blood smear strongly suggests asplenia,[139,140] although they are occasionally present in normal infants in the first week of life.[141] Absence of the spleen can be inferred from the inability to demonstrate its presence by ultrasonography,[52,53] computed tomography,[52,53,142] or radionuclide scans.[143–145] But there have been no prospective stud-



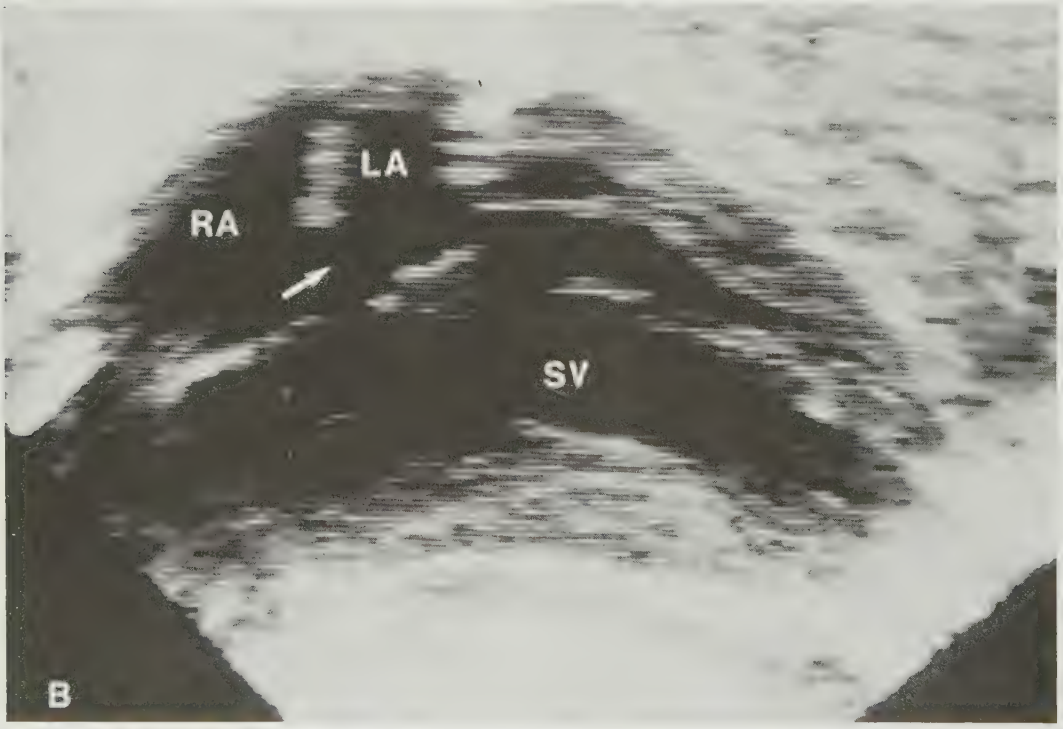


Fig. 75–8. Chest roentgenogram (A) and echocardiogram in cyanotic neonate with asplenia. The chest roentgenogram reveals pulmonary edema with a left-sided heart and right-sided stomach (note nasogastric tube). Subcostal four-chamber view of echocardiogram (B) demonstrates an ostum primum-type atrial septal defect (arrow), a common atrioventricular valve, and a single ventricle (SV). The aorta (not pictured) was anteriorly located; the pulmonary valve was atretic.

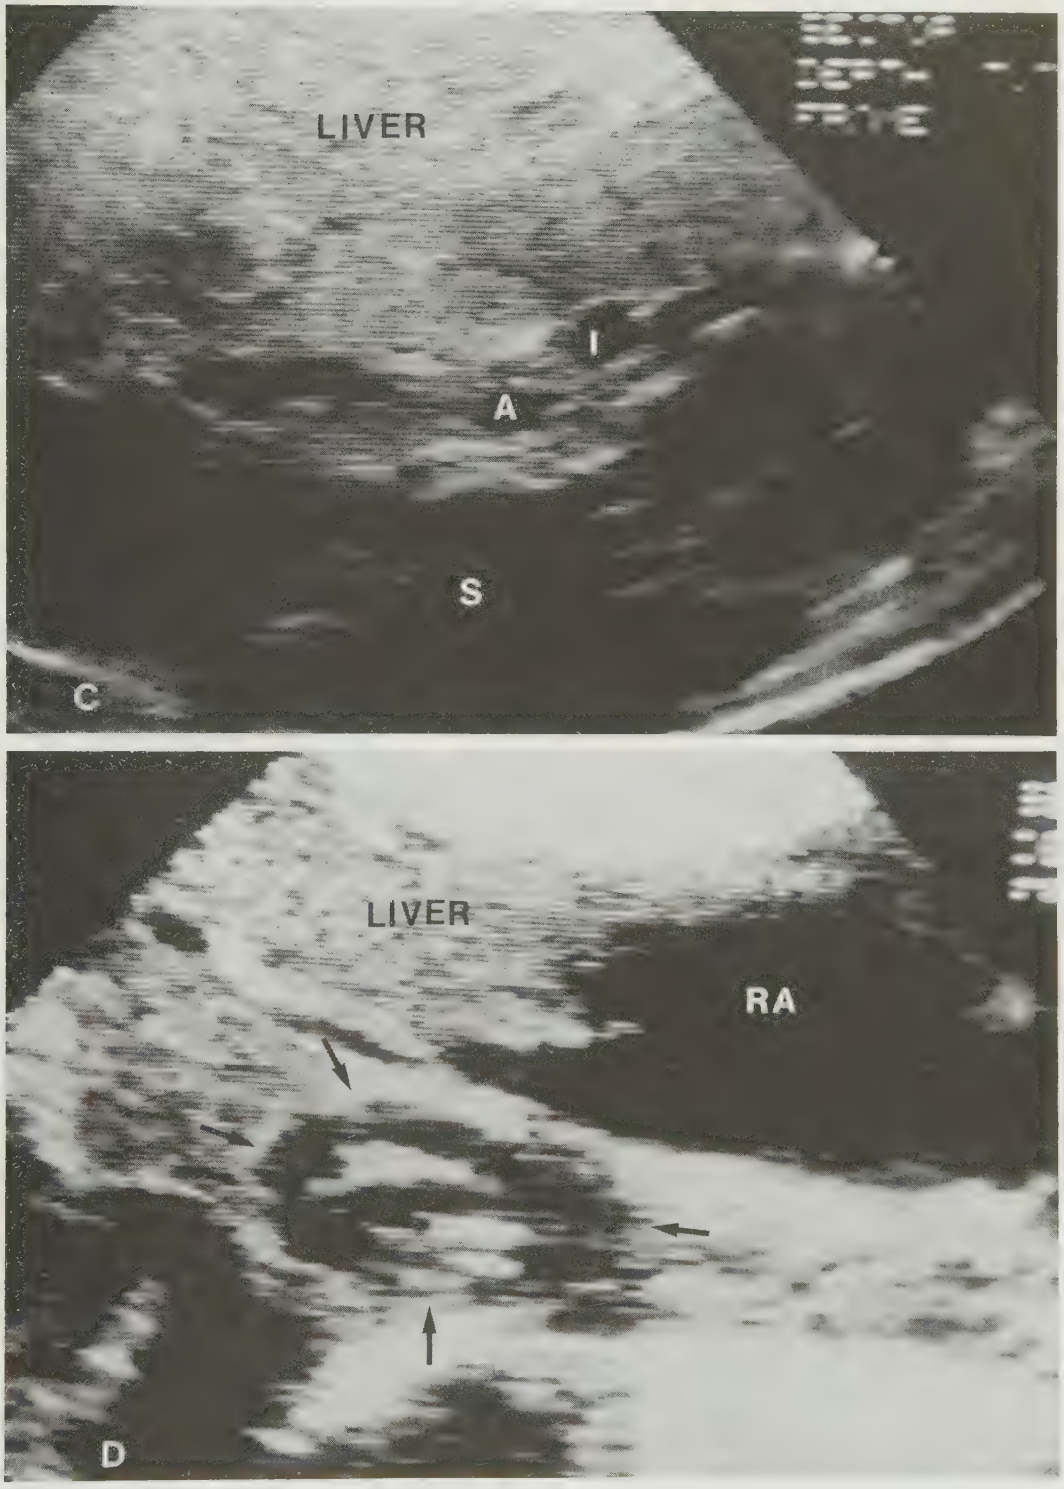

Fig. 75–8 (cont.) A transverse ultrasonic scan (C) just below the diaphragm shows the abdominal aorta (A) and inferior vena cava (I) juxtaposed on the left side of the spine (S). A parasagittal scan (D) reveals a vascular plexus (arrows) where the common pulmonary vein joins the portal system beneath the liver. RA = right atrium, LA = left atrium.

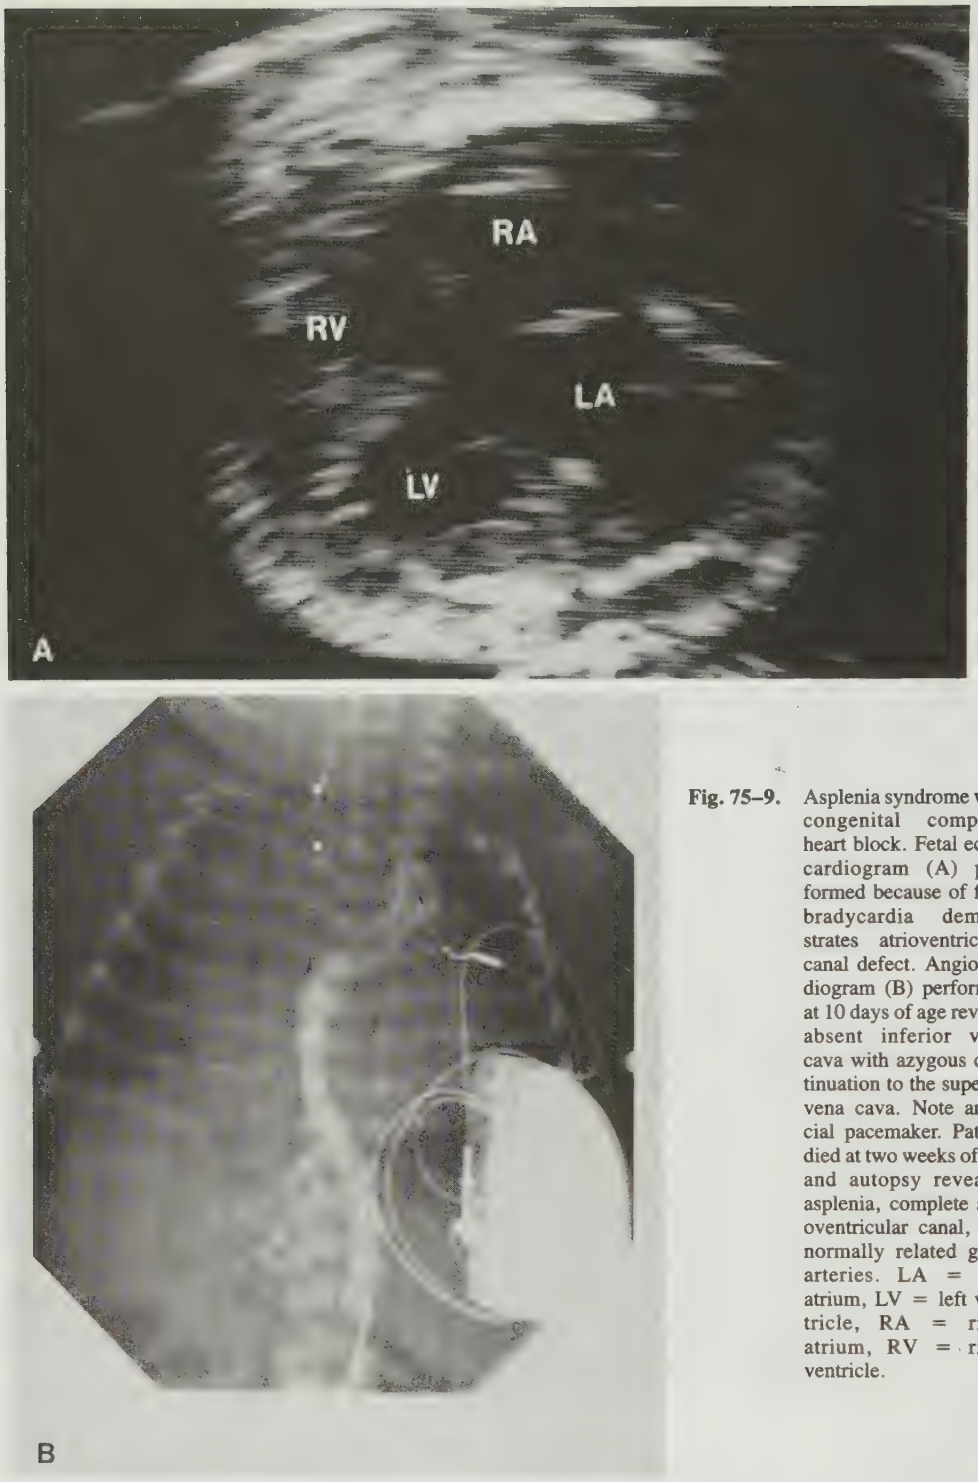

Fig. 75–9. Asplenia syndrome with congenital complete heart block. Fetal echocardiogram (A) performed because of fetal bradycardia demonstrates atrioventricular canal defect. Angiocardiogram (B) performed at 10 days of age reveals absent inferior vena cava with azygous continuation to the superior vena cava. Note artificial pacemaker. Patient died at two weeks of age and autopsy revealed asplenia, complete atrioventricular canal, and normally related great arteries. LA = left atrium, LV = left ventricle, RA = right atrium, RV = right ventricle.

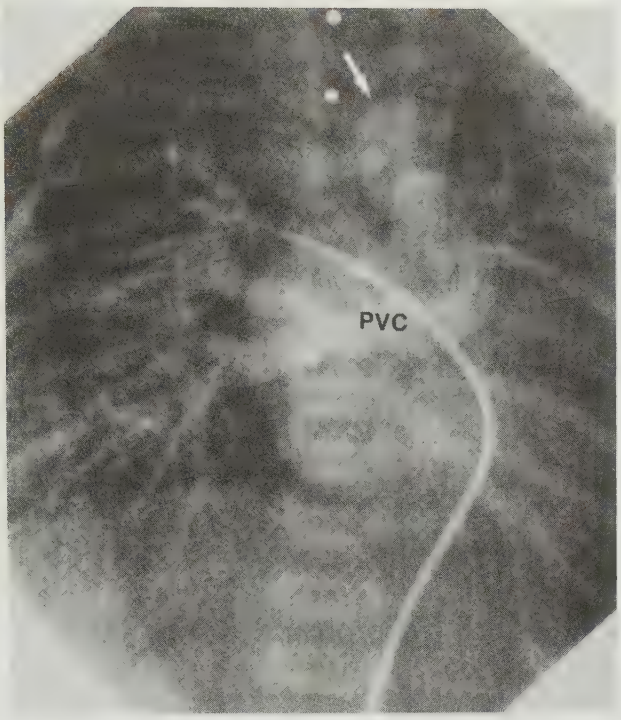

Fig. 75–10. Venous phase of pulmonary arteriogram in 6-week-old infant with asplenia syndrome. The pulmonary venous confluence (PVC) drains superiorly and enters the right superior vena cava (arrow). Pulmonary venous obstruction at this site produced severe pulmonary hypertension. The patient died at 3 months of age; autopsy revealed complete atrioventricular canal defect and transposition of the great arteries. The right lung had two lobes and the left had three lobes.

ies of the specificity or sensitivity of these techniques in proving asplenia. In clinical practice, asplenia often is assumed when features of right isomerism are present (in particular, radiographic features of right pulmonary isomerism), coupled with a complex intracardiac lesion and the presence of the inferior vena cava and abdominal aorta on the same side of the spine.[146]

Associated Cardiovascular Abnormalities

The typical cardiovascular anomalies are listed in Table 75–4. Atrioventricular canal, transposition (at least in the sense of an anterior aorta), and pulmonary stenosis or atresia are almost invariable features. At least 75% of cases have total anomalous pulmonary venous connection. A high percentage of cases (but not all) have right pulmonary isomerism. The presence of an inferior vena cava and abdominal aorta on the same side of the spine is nearly pathognomonic for asplenia,[146] although there are exceptions to this finding as well (Fig. 75–11). Left heart obstructive lesions, including aortic atresia have been reported[114,153,154] but are uncommon.

Immunologic Status

The role of the spleen in combatting infection, particularly from encapsulated organisms, is well-recognized. Thus, it is not surprising that patients with asplenia are particularly susceptible to overwhelming bacterial infection. In a review of cases of congenital asplenia at the Boston Children's Hospital, Waldman et al.[155] found that after the first month of life, patients with asplenia syndrome were at greater risk of dying from infection than from their heart disease. Older children with asplenia syndrome may also have deficiencies of IgM and IgE and suboptimal responses to pneumococcal vaccine.[156] Thus, in patients whose cardiac disease suggests asplenia syndrome, appropriate studies (hematologic, ultrasonic, radionuclide) should be performed to demonstrate the presence or absence of a spleen. If asplenia is documented or strongly suspected, the patient should receive prophylactic antibiotics. In the first six months of life, coverage against gram-negative and gram-positive organisms is recommended and ampicillin is used most commonly. Penicillin alone generally is sufficient for older infants and children. Administration of pneumococcal and hemophilus influenza vaccines likewise are recommended, with serologic testing to confirm an adequate response.[156]

Table 75–4. Incidence of Cardiovascular Abnormalities in the Asplenia and Polysplenia Syndromes

	Asplenia	*Polysplenia*
Dextrocardia	40%	40%
ASD/common atrium	90%	80%
Single ventricle	50%	10%
AV canal	85%	40%
TGA	80%	30%
PS/PA	80%	30%
LVOTO	Rare	40%
Bilat SVC	50%	40%
Absent IVC	Rare	70%
TAPVC	70%	Rare
PAPVC	Rare	40%
Right pulmonary isomerism	70%	10%
Left pulmonary isomerism	Rare	60%

Note: Percentages listed are approximations based on 300 cases of asplenia[2,21,124,131,138,150,151] and 247 cases of polysplenia.[2,21,150–152] Differences in terminology preclude precise numerical tabulation.

Key: ASD = atrial septal defect, AV canal = atrioventricular canal; TGA = transposition of the great arteries; PS/PA = pulmonary stenosis or atresia; LVOTO = left ventricular outflow tract obstruction; SVC = superior vena cava; IVC = inferior vena cava; TAPVC = total anomalous pulmonary venous connection; and PAPVC = partial anomalous pulmonary venous connection.

Management and Prognosis

The most common presentation of the asplenia syndrome is that of an intensely cyanotic neonate with a complex intracardiac lesion consisting of atrioventricular canal, transposition of the great arteries, and pulmonary stenosis or atresia. Initially, survival is often dependent upon creation of a systemic-to-pulmonary anastomosis to increase pulmonary blood flow. Management is complicated by the presence of an obstructed total anomalous pulmonary venous connection in many patients, often obscured by the diminished pulmonary blood flow pre-operatively. These patients may progress from intense cyanosis before a systemic-to-pulmonary anastomosis to severe pulmonary edema afterward due to the obstructed total anomalous pulmonary venous connection. Freedom et al.[157] have used a prostaglandin infusion to unmask venous obstruction pre-operatively.

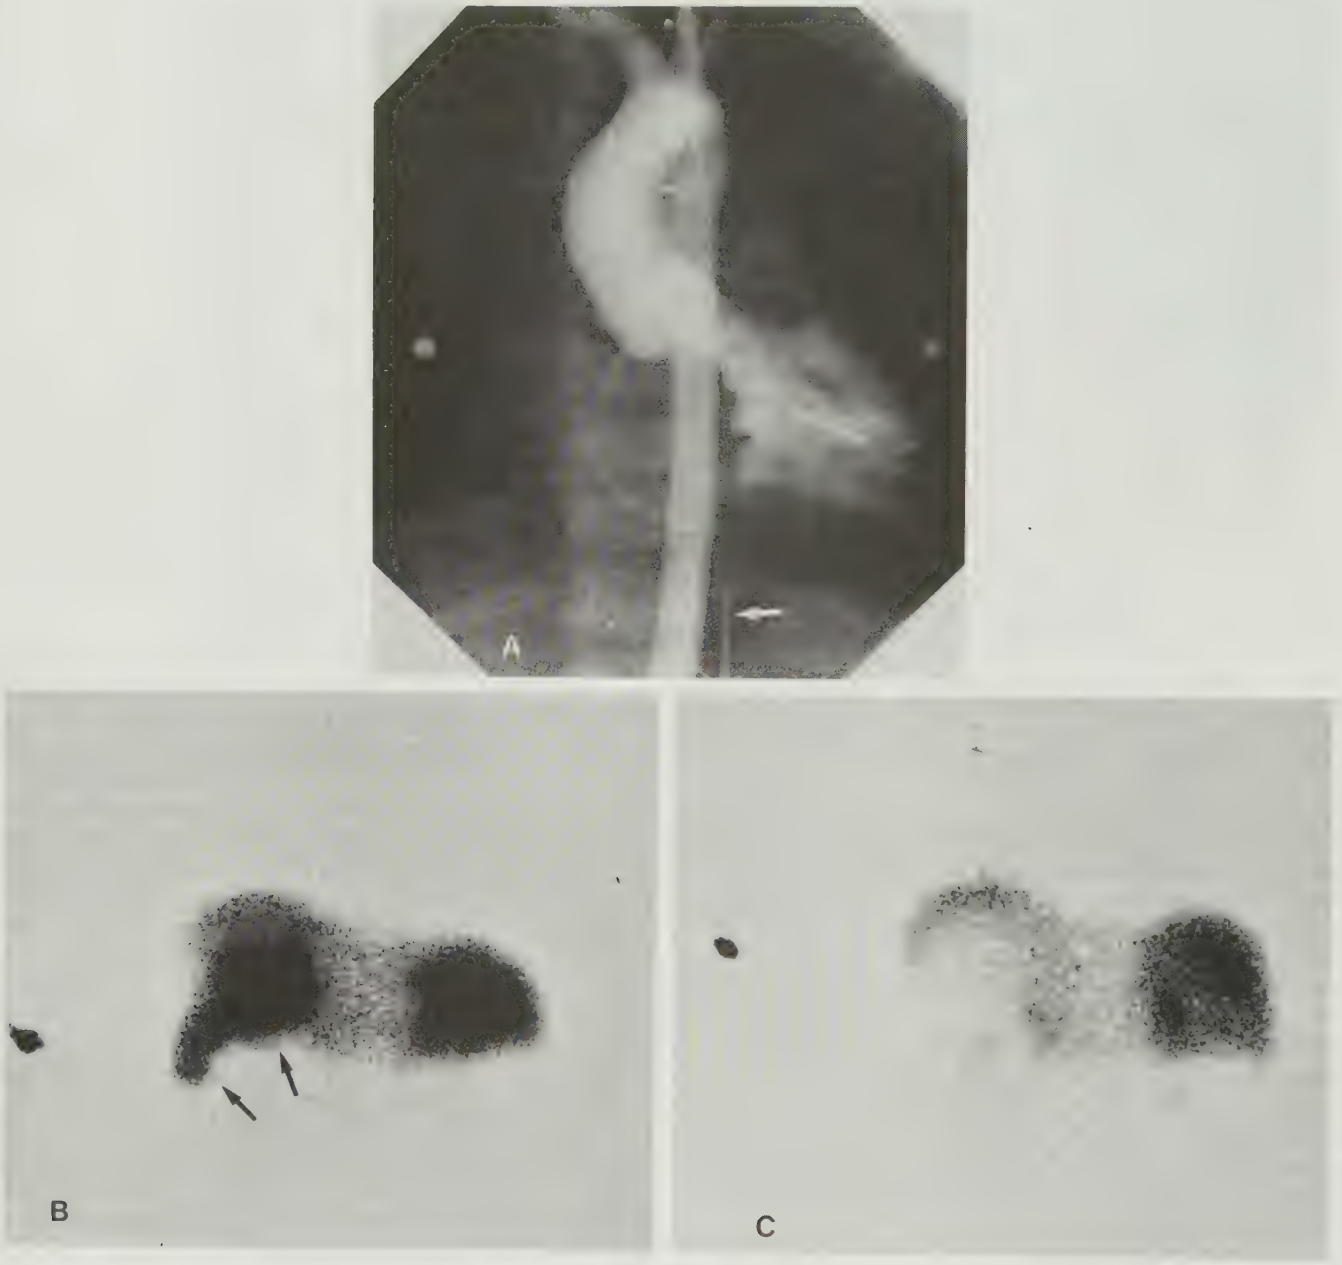

Fig. 75–11. Angiocardiogram (A), Tc^{99m} sulfur colloid liver/spleen scan (B), and Tc^{99m} disofenin (hepato-biliary) scan (C) in a 4-year-old boy with partial atrioventricular canal defect (common atrium) and situs inversus of the abdominal viscera. Left ventricular angiocardiogram reveals intact ventricular septum and the typical "scalloped" appearance of the left atrioventricular valve. Note that both the catheter in the inferior vena cava (arrow) and the abdominal aorta are on the left side of the spine. The sulfur colloid liver spleen scan reveals a left-sided liver and an additional irregular mass (arrows) in the right upper quadrant. Failure to visualize this mass on the hepato-biliary scan (C) suggests that it is splenic tissue (probably polysplenia). (Radionuclide scans courtesy of Dr. C.D. Teates.)

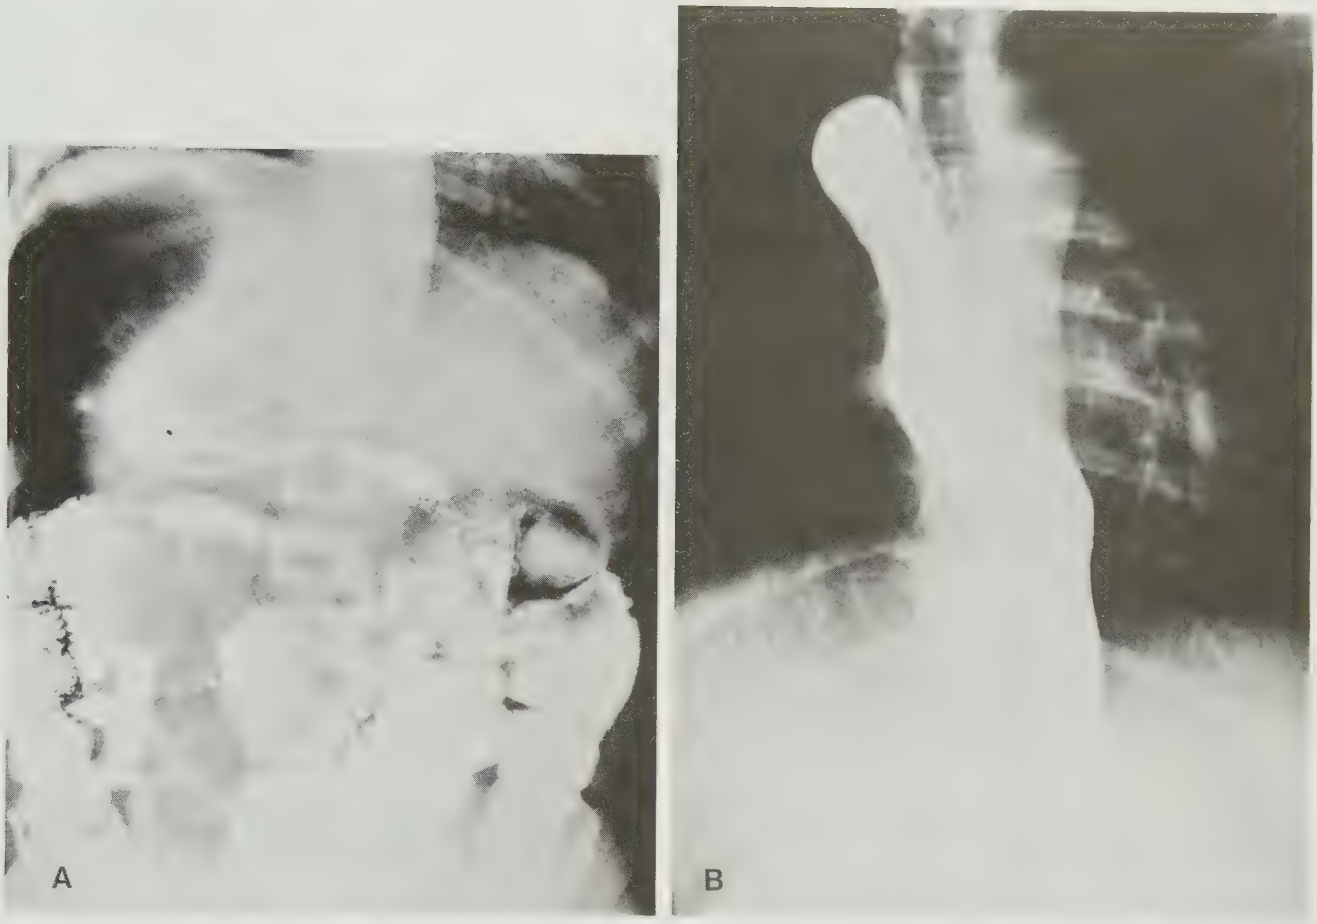

Fig. 75–12. Heterotaxia with azygous continuation of the inferior vena cava in an asymptomatic 35-year-old woman. Barium swallow (A) reveals stomach on right, liver on left, with malrotation of bowel. Venous angiogram (B) demonstrates azygous vein, which is on left side in abdomen, crosses to right at level of the diaphragm, and joins superior vena cava in the mediastinum. Heart is left-sided, and intracardiac anatomy was normal. Polysplenia is a diagnostic consideration but its confirmation was not undertaken.

Theoretically, the cardiac anomalies typical of the asplenia syndrome are amenable to intracardiac repair using modifications of the Fontan technique[158–161] or intricate intra- and extracardiac baffles.[161,162] The operative mortality is substantially higher in heterotaxy than in tricuspid atresia or single ventricle and is higher in patients with asplenia than in those with polysplenia.[159]

In view of the complexity of the intracardiac lesions and the decreased immune function, it is not surprising that the prognosis for infants with asplenia syndrome is poor. The mortality rate for typical asplenia syndrome approaches 80% in the first year of life.[2,150] One-year survival rates for "heterotaxy" (probably more heavily weighted by asplenia than polysplenia) were 43 and 54% at the Boston Children's Hospital[163] and the Texas Children's Hospital,[164] respectively, despite medical and surgical therapy. Exceptions have been reported,[165] and one patient known to many of the authors of this text died at Texas Children's Hospital at 32 years of age.

Polysplenia Syndrome

Clinical Features

There is much more variability in the presentation of patients with polysplenia than in those with asplenia. Since pulmonary stenosis and transposition are relatively infrequent, cyanosis usually is not severe and symptoms of congestive heart failure from large left-to-right shunts predominate. Other patients may be asymptomatic and a substantial number of patients may have no cardiac disease at all (Fig. 75–12). Several reports have described associated gastrointestinal anomalies, particularly extrahepatic biliary atresia.[166–168]

The findings on physical examination are not specific for polysplenia and reflect the associated cardiac abnormalities (see Table 75–4).

The chest roentgenogram may suggest the presence of the polysplenia syndrome (Fig. 75–13). Absence of the hepatic portion of the inferior vena cava with azygous continuation, a common feature in polysplenia, can be predicted from the presence of mediastinal "knuckle" (where the azygous vein joins the superior vena cava) (see Fig. 75–12A) especially when coupled with absence of the normal inferior vena cava shadow on the lateral view,[169,170] although the reliability of the latter finding has been questioned.[171]

Especially if it is suggestive of left pulmonary isomerism, bronchial symmetry is a more specific finding. Cardiac malposition or discordance between the cardiac apex and the stomach suggest

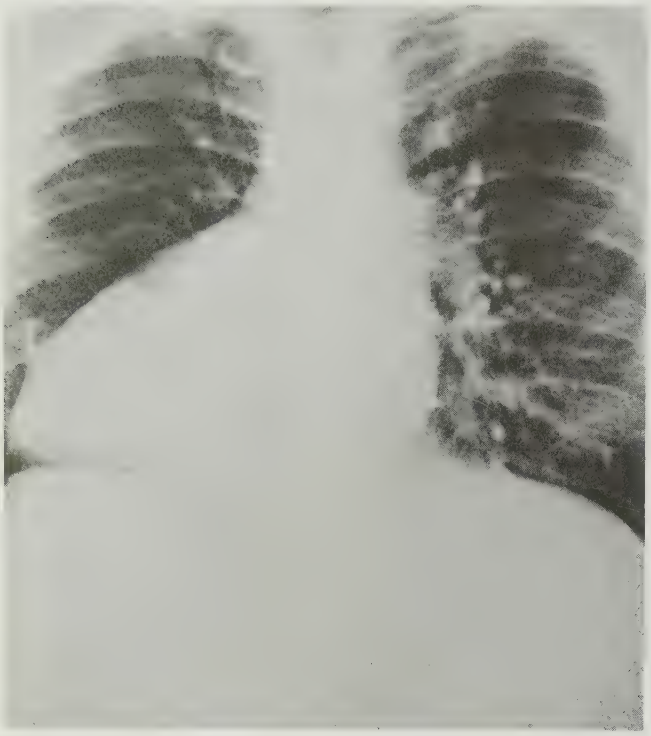

Fig. 75–13. Dextrocardia in an adult with polysplenia. Patient died of arrhythmia at 41 years of age. Autopsy demonstrated left pulmonary isomerism, complete atrioventricular canal, pulmonary stenosis, and transposition of the great arteries. A Blalock-Taussig anastomosis and a pulmonary valvotomy had been performed in early childhood.

heterotaxy in general, but are not particularly useful in distinguishing polysplenia from asplenia.

Electrocardiographic abnormalities are common in polysplenia. Since the sinus node is a right atrial structure, it is not surprising that left atrial isomerism is characterized by an absent, displaced, or hypoplastic sinus node.[136] As a result, the frontal plane P vector typically is oriented leftward and superiorly.[134–136,172,173] The course of the conduction system is abnormal,[136,174] and congenital complete AV block is present occasionally.[135,175] The QRS axis and precordial leads reflect 1) the position of the heart in thorax and 2) the nature of the intracardiac lesions. A superiorly oriented frontal plane QRS axis reflecting atrioventricular canal defect is a common finding.[136]

Many of the cardiac, great vessel, and visceral abnormalities associated with polysplenia can be demonstrated by echocardiography.[78,176,177] Although one would like to demonstrate anatomic features of left atrial isomerism, the atrial appendages generally cannot be imaged by echocardiography in sufficient detail to make this determination. In practice, the presence of polysplenia has been inferred from the absence of the hepatic portion of the inferior vena cava with azygous continuation. This vascular anomaly also may occur in the asplenia syndrome, but the latter can be excluded by sonographic demonstration of splenic tissue. (Fig. 75–14).

Ideally, the diagnosis of polysplenia (as opposed to heterotaxy in general or left isomerism) would be made by demonstration of multiple spleens. This can be accomplished in some patients by radionuclide scans,[143,144] although it may be difficult to distinguish two closely related spleens from one large spleen (see Fig. 75–11). The technique is more valuable to prove the presence of some splenic tissue (and thus exclude asplenia) than to diagnose polysplenia itself. More recently, computed tomography has been used to demonstrate the presence of multiple spleens[53,178] (Fig. 75–15). Visceral arteriography can be used to demonstrate polysplenia,[177] but this technique largely has been replaced by less invasive methods.

Associated Cardiovascular Abnormalities

The intracardiac and vascular abnormalities occurring in polysplenia syndrome are summarized in Table 75–4. Although there is considerable overlap, certain features occur with much higher frequency in either asplenia or polysplenia, fostering the notion that these conditions represent "syndromes." Atrioventricular canal defect is common to both conditions. In polysplenia, absence of the hepatic portion of the inferior vena cava is very common, as is partial anomalous pulmonary venous connection. Pulmonary stenosis or atresia is uncommon in polysplenia and, normally, related great arteries are more common than transposition. Left-sided obstructive lesions occur more frequently in the polysplenia syndrome than with asplenia.

Management and Prognosis

Many of the cardiac abnormalities associated with polysplenia are amenable to surgical correction, with low mortality. In some children with polysplenia, splenic function may not be normal; therefore, functional tests (e.g., Howell-Jolly bodies) should be performed in these patients as well.

There is a general perception that the prognosis in polysplenia is better than that for asplenia,[2,152,180] although in either case the prognosis is largely determined by the intracardiac anomalies. Rose et al.[150] found low one-year survival rates among infants with asplenia (21%) and those with polysplenia (39%). However, some individuals with polysplenia have minor cardiac abnormalities[152,181] and presumably have a normal or near-normal life expectancy.

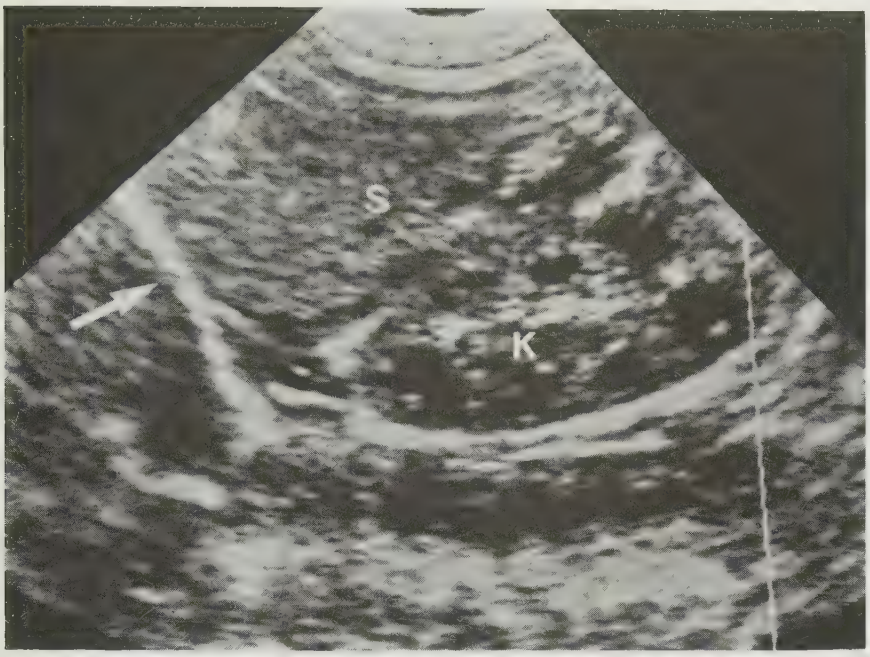

Fig. 75–14. Abdominal ultrasonogram in a neonate with cyanosis, situs inversus of abdominal viscera, and levocardia. This right parasagittal scan demonstrates splenic tissue between the right kidney (K) and the right hemidiaphragm (arrow). Patient's head is toward the left, feet toward the right of illustration. (Courtesy of Dr. Joan McIlhenny.)

Exceptions

Although the concept of asplenia and polysplenia as distinct syndromes has some clinical utility, it is important to realize that many "crossover" cases exist and there is nothing to suggest a causal relationship between the absence of the spleen (or the presence of several) and congenital heart disease. The heart may be completely normal in the presence of asplenia.[155,182–185] Conversely, many of the features of the "asplenia syndrome" have been reported in the presence of a normal or rudimentary spleen.[186,187]

Certain cardiovascular abnormalities occur with such a high frequency that they are often considered pathognomonic for asplenia or polysplenia. The presence of the inferior vena cava and abdominal aorta on the same side of the spine has been considered specific for asplenia,[146] but the patient with this finding depicted in Figure 75–11 clearly has splenic tissue. Similar examples have been described by others.[180,188] Likewise, although azygous continuation of the inferior vena cava is strongly suggestive of polysplenia, the patient depicted in Figure 75–9 had asplenia at autopsy. An attempt by Landing and colleagues[189–191] to explain exceptional cases by creation of additional syndromes (m-, f-, and o-anisosplenia) has not been adopted widely.

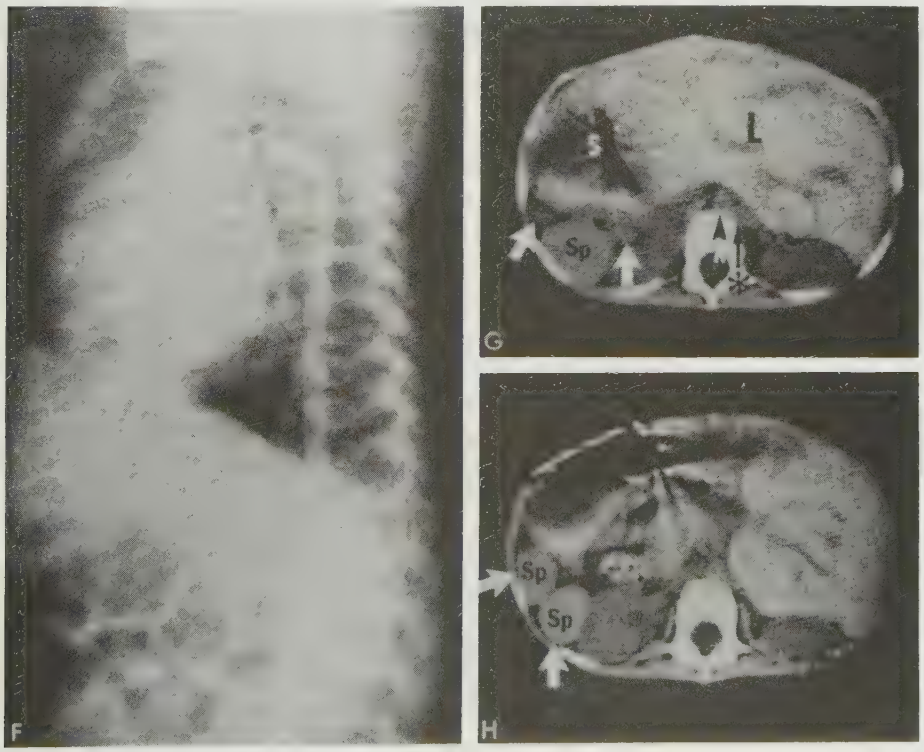

Fig. 75–15. Angiocardiogram and computed tomographic (CT) scan in polysplenia. The lateral projection of the angiocardiogram (F) demonstrates the frequent finding of azygous continuation of the inferior vena cava. The CT scan (G and H) shows a left-sided liver (L) and abdominal aorta (A) and a right-sided stomach (S). Several masses of splenic tissue are apparent (Sp, arrows). The asterisk indicates the location of the azygous vein on the CT scan (G). (From Tonkin, I.L.D., The definition of cardiac malpositions with echocardiography and computed tomography. *In* Pediatric Cardiac Imaging. Edited by W.F. Friedman and C.B. Higgins. Philadelphia, W.B. Saunders, 1984, pp. 157–187. Reproduced with permission.)

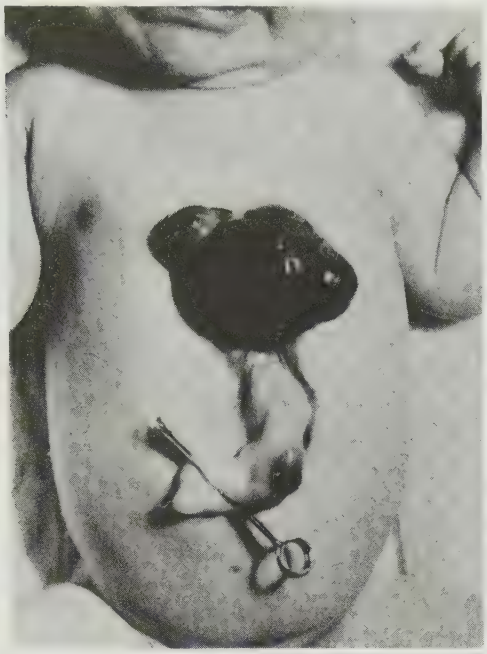

Fig. 75–16. Frontal (upper) and lateral (lower) views of newborn infant with thoracic ectopia cordis. Patient died after attempt to place heart in left pleural space. Intracardiac anatomy was normal except for a left superior vena cava and patent ductus arteriosus. (From Milhouse, R.F., and Joos, H.A.: Extrathoracic ectopia cordis: Report of cases and review of literature. Am. Heart J., *57*:470, 1959. Reproduced with permission.)

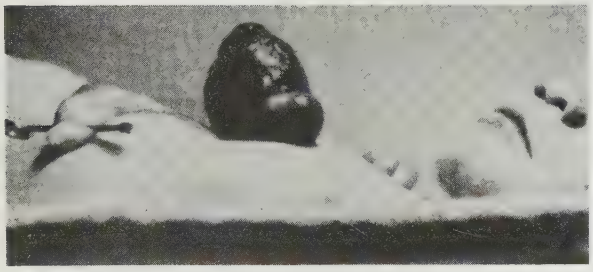

Although the asplenia syndrome has features of bilateral right-sidedness, and polysplenia simulates bilateral left-sidedness, numerous exceptions to this rule occur. Only 60 to 70% of patients with polysplenia actually have two morphologic left lungs (see Table 75–4). Additionally, the bronchi and atria may be discordant[192] and *left* atrial isomerism has been described in a patient with asplenia.[193]

ECTOPIA CORDIS

Historical Aspects

Ectopis cordis is the rarest and certainly the most dramatic of the cardiac malpositions. Byron[194] found only 142 cases reported prior to 1948. The earliest report is by Niels Stensen, whose 1671 description of the internal anatomy of the ectopic heart also appears to be the first account of the anomaly now known as the tetralogy of Fallot.[195] Greig's[196] review covers virtually all cases published before 1926. He credits Todd (1836) and Townsend (1845) with classification of ectopia cordis into three types: 1) cervical; 2) thoracic; and 3) abdominal. More recently, a fourth type, thoraco–abdominal, has been described.[194] Many of the earlier reports of abdominal ectopia cordis were probably of the thoraco–abdominal type, with true abdominal ectopia cordis being extremely rare.

Embryology

All forms of ectopia cordis appear to represent incomplete fusion of the converging lateral body walls in the midline. The defect may be established as early as the third week of gestation when the demarcation between intra- and extraembryonic coelom is established.[199] Simple failure of the sternal precursors to fuse completely in the midline results in mild or partial forms of ectopia cordis in which the sternal defect is covered with skin and the heart is palpable (or even visible), but not actually protruding from the thorax.

The complete forms of ectopia cordis may occur as a result of the heart being "trapped" outside of the thorax as the lateral body walls converge in the midline.[199] The thoraco–abdominal forms of ectopia cordis appear to represent failure of fusion of the lower sternum and defective development of the septum transversum, which forms the anterior portion of the diaphragm.[199–201]

Intracardiac Anatomy

Intracardiac abnormalities are very common, but not invariable, in patients with ectopia cordis. Atrial septal defect, ventricular septal defect, tetralogy of Fallot, and tricuspid atresia are the most common intracardiac defects.[194–197,200–205] An additional malfor-

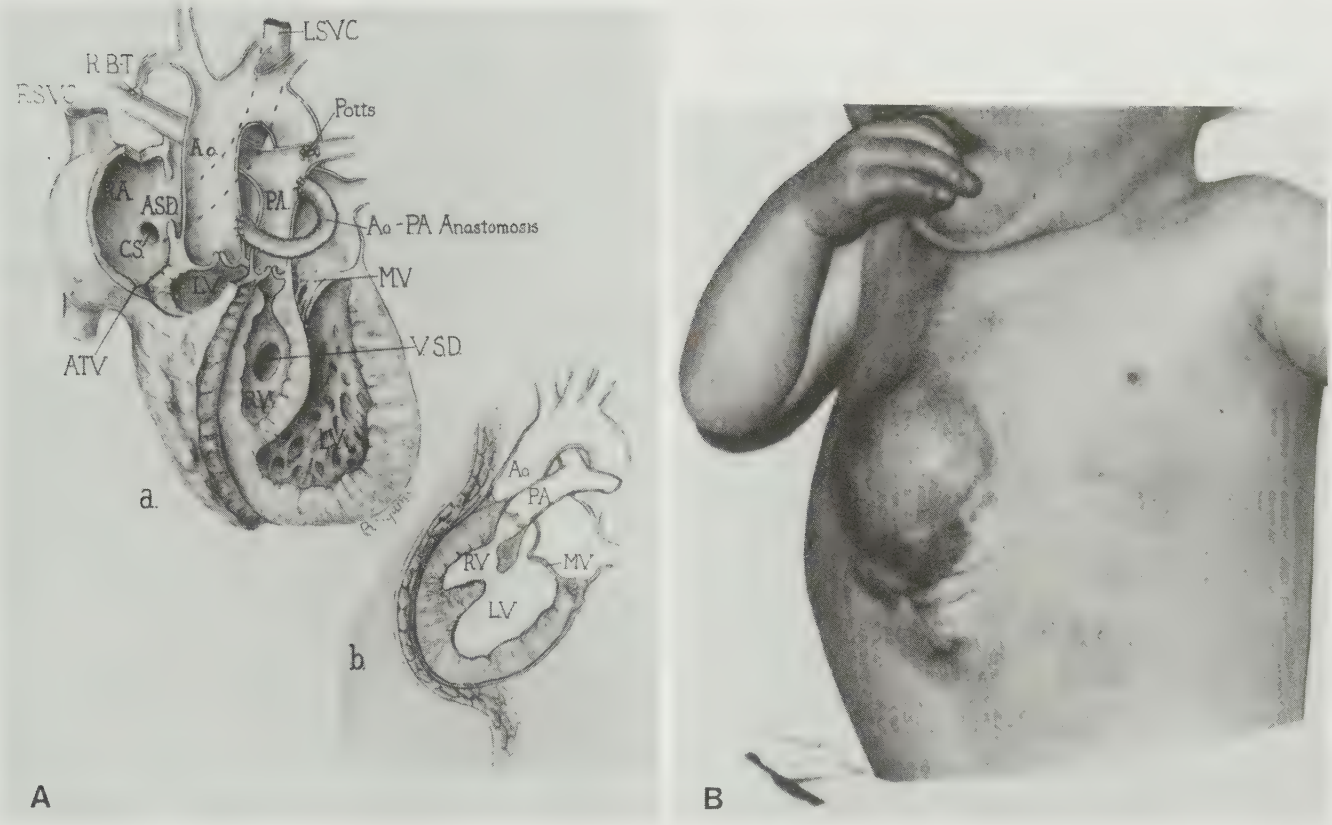

Fig. 75–17. Thoraco-abdominal ectopia cordis with tricuspid atresia. On the first day of life, an operation was performed and a large omphalocoel was covered with skin. Cardiac catheterization revealed tricuspid atresia with pulmonary stenosis (A), which was treated with a series of systemic-pulmonary artery anastomoses. At 13 months of age (B), the residual midline defect was apparent: Most of the left and right ventricles were still outside of the thorax. Patient also had the mosaic form of Turner's syndrome. Ao = aorta; ASD = atrial septal defect, ATV, atretic tricuspid valve, CS = coronary sinus, LSVC = left superior vena cava, LV = left ventricle, MV = mitral valve, PA = pulmonary artery, RA = right atrium, RBT = right Blalock–Taussig anastomosis, RSVC = right superior vena cava, RV = right ventricle, VSD = ventricular septal defect. (From Garson et al. Thoracoabdominal ectopia cordis with mosaic Turner's syndrome: Report of a case. Pediatrics, *62*:218, 1978. Reproduced by permission of Pediatrics.)

mation, a diverticulum protruding from the apex of the left ventricle, is present in 20% of the patients with the thoraco–abdominal defect,[206–209] and is virtually never present in other subjects, with or without ectopia cordis.

Treatment and Prognosis

The treatment and prognosis in ectopia cordis are largely determined by three variables: 1) the location of the defect; 2) the extent of the cardiac displacement; and 3) the intracardiac anatomy. Simple sternal clefts with absent or minimal cardiac protrusion can be repaired in early infancy with direct opposition of the edges of the defect or use of a prosthetic mesh.[201,210] At the other extreme, complete protrusion of the heart through a sternal defect—ectopia cordis extrathoracica nuda—is almost invariably fatal (Fig. 75–16). Ravitch[201] found descriptions of 20 operated patients with only 2 survivors; Van Praagh[21] described a third survivor.

The thoraco–abdominal form of ectopia cordis (Fig. 75–17) lies between these extremes. Typically, the lesion exists as part of a constellation of associated anomalies, which several investigators believe should be distinguished from ectopia cordis.[200,201,205,208] The lesions include: 1) midline supra-umbilical abdominal defect; 2) defect of the distal sternum; 3) deficiency of the diaphragmatic pericardium; 4) deficiency of the anterior diaphragm; and 5) congenital intracardiac abnormality, a constellation of anomalies sometimes referred to as the pentalogy of Cantrell.[200] The presence of an omphalocoel, as opposed to simple umbilical hernia, is an important risk factor and requires immediate surgical therapy.[211,213]

Patients without omphalocoel or intracardiac defects may remain largely asymptomatic and can undergo surgical repair later in childhood.[214] The major difficulty in repair of this and other forms of ectopia cordis is cardiorespiratory insufficiency following attempts to force the heart into the thorax.[215]

ACKNOWLEDGMENTS

The author is indebted to his former colleagues in Houston and his present colleagues in Charlottesville for many of the concepts advanced in this chapter. The chapter was typed and edited by Marjorie Hampton.

CHAPTER 76

Clinical Physiology of Obstructive and Regurgitant Lesions

Kenneth O Schowengerdt, Jr
J Timothy Bricker

Valvular abnormalities account for most obstructive and regurgitant lesions in childhood. The remainder of cases are characterized by obstructions proximal or distal to the valves. The clinical importance of an obstructive or regurgitant lesion is determined by the anatomic site of obstruction, the severity of the obstruction, or amount of regurgitation, the presence of other cardiac abnormalities (such as other obstructive or regurgitant lesions or shunts), the age of the patient, and the status of the patient's myocardial function.

ANATOMIC LOCATION OF THE LESION

The anatomic location of an obstruction influences the clinical manifestations in a number of ways. An obstructive lesion in the systemic venous system causes venous plethora and edema in the segment drained by the obstructed venous segment. Consider as an example a case of superior vena caval obstruction syndrome from a thrombus in the superior vena cava. Obstruction within the right atrium (e.g., from a right atrial myxoma or thrombus) and tricuspid valve stenosis also may cause systemic venous congestion and peripheral edema. Right ventricular outflow obstruction may be due to valve obstruction or may result from abnormal muscle in the right ventricle below the pulmonary valve. Differences in natural history, physiology, and management exist based on different anatomic locations of the right ventricular outflow obstruction. Pulmonary valve stenosis is easier to treat (i.e., with balloon valvuloplasty) than is subvalvular right ventricular outflow tract obstruction (which requires myomectomy). Subpulmonic, infundibular obstruction often becomes progressively severe. Although the severity of valve pulmonary stenosis also may progress in some cases, it is comparatively uncommon for valve pulmonary stenosis to worsen over the years. Obstructions may occur above the pulmonary valve as well. Supravalvular stenosis is generally diffuse and may extend to the branch pulmonary arteries. A single, narrow, discrete obstruction of the pulmonary trunk is uncommon (except for the case of a surgically placed pulmonary artery band) in contrast to the typically localized nature of aortic coarctation. Distal pulmonary artery stenosis may complicate or preclude surgical therapy.

There are several anatomic locations of lesions that cause obstruction of return of the pulmonary venous blood to the left ventricle as discussed in Chapter 77; Cor Triatriatum, Pulmonary Vein Obstruction, Supravalve Mitral Stenosis, and Congenital Mitral Valve Disease. Included are cases of pulmonary vein stenosis, pulmonary vein atresia, anomalous pulmonary venous return with obstruction (either intracardiac or extracardiac), baffle obstruction from a Mustard or Senning operation, cor triatriatum, supravalvar mitral membrane, and mitral stenosis. Pulmonary venous hyper-

Table 76–1. Factors Determining the Clinical Significance of an Obstructive or Regurgitant Lesion

Anatomic locations of the lesion
Magnitude of the lesion (severity of obstruction or amount of regurgitation)
Presence of other hemodynamic burdens (other obstruction or regurgitation or shunt)
Age of the patient
Impairment of myocardial contractility

tension causes stiff lungs which increase the work of breathing. Symptomatic pulmonary edema with tachypnea and wheezes are common in these lesions, which are sometimes confused with lung disease. Pulmonary arterial hypertension develops as does pulmonary arteriolar hypertension, resulting in physical findings of pulmonary hypertension and right ventricular pressure overload.

Left ventricular outflow obstruction may be at the subvalve, valve, supravalve, or aortic level. Common to these obstructions is an increased afterload for the left ventricle. Ventricular hypertrophy, ventricular dilation, and impaired ventricular function will result, depending upon the chronicity and severity of obstruction. Subaortic obstruction may be associated with aortic regurgitation and thus has clinical significance beyond the severity of left ventricular outflow tract obstruction per se. An obstruction proximal to the coronary artery ostia (such as subvalvular or valvular aortic stenosis) is more likely to be associated with a myocardial blood flow demand/supply mismatch and myocardial ischemia than is a left ventricular outflow obstruction beyond the coronary ostia (such as supravalvar aortic stenosis or coarctation of the aorta).

This has been suggested to be of clinical importance for the infant with both severe coarctation of the aorta and severe aortic stenosis as one proposes a strategy for a surgical intervention upon one or both lesions. Poststenotic dilation of the ascending aorta can reach aneurysmal proportions in aortic valve stenosis and require surgery on the aorta in adult years in rare instances. The anatomic location of coarctation of the aorta will affect the management strategy in some coarctation cases as discussed in Chapter 80, Coarctation of the Aorta and Interrupted Aortic Arch, and Chapter 131, Surgical Decision Making. The site of coarctation obstruction in relation to the ductus arteriosus is of clinical importance prior to closure of the ductus or if one attempts to use prostaglandin E1 for stabilization of an infant with a severe coarctation of the aorta. The anatomic site of coarctation relative to the subclavian arteries will be of importance if one plans to use the subclavian artery in the repair. Hypoplasia of the aortic isthmus may be present with infant coarctations (''coarctation syndrome''), as discussed in Chapter 80, Coarctation of the Aorta and Interrupted Aortic Arch, and may be an important source of residual obstruction after a technically adequate repair of coarctation of the aorta in the newborn.

The location of a regurgitant lesion also influences the clinical manifestations. Tricuspid regurgitation of mild and moderate severity is tolerated very well. Severe tricuspid regurgitation (particularly if associated with right ventricular hypertension) causes systemic venous congestion. Chronic right atrial enlargement from tricuspid regurgitation may lead to atrial flutter or fibrillation. Isolated pulmonary regurgitation generally is tolerated quite well. Although there may be deleterious consequences of long-standing right ventricular volume overload and extremely long followup is unavailable, in most cases, even severe pulmonary regurgitation seems to be tolerated surprisingly well after pulmonary valvectomy for pulmonary valve stenosis or after transannular patch for tetralogy of Fallot. If it is severe, mitral regurgitation causes left atrial hypertension with symptoms of pulmonary edema. Severe mitral regurgitation will cause left atrial dilation and may result in atrial arrhythmias. The high velocity left ventricular to left atrial jet occasionally is associated with intravascular hemolysis—particularly if prosthetic patches or valves have been implanted. Mitral regurgitation is a lesion that results in an afterload reduction for the left ventricular myocardium. Surgical correction of severe mitral regurgitation can increase the afterload of the left ventricle and—in the presence of impaired left ventricular myocardial function before surgery—result in a severely compromised patient in the postoperative unit. Severe aortic regurgitation, in contrast, is a volume load on the left ventricle. Surgical treatment of the case with severe aortic regurgitation and myocardial failure is tolerated better, from the aspect of ventricular function, than surgical treatment of the case of severe mitral regurgitation with myocardial failure.

MAGNITUDE OF THE LESION

It is intuitive that the more severe a given lesion, the more likely it is to be clinically important. How one assesses the severity of an obstruction is less intuitively obvious. Clinical features may give clues to the severity of an obstruction. With increasing severity of semilunar valve stenosis, the murmur generally becomes louder and peaks later in systole. The most severe obstructions will be associated with a very soft murmur because of low cardiac output due to the critical valve obstruction and/or ventricular dysfunction. The severity of a valvular lesion is assessed clinically by the consequences proximal to the obstruction. For example, ascites hints at the severity of tricuspid stenosis and wheezing or tachypnea from pulmonary venous hypertension reflects the severity of mitral stenosis. In aortic or pulmonary stenosis, ventricular hypertrophy with decreased compliance may be responsible for reduced filling and reduced cardiac output. The low cardiac output from critical obstruction may obscure the diagnosis or cause confusion in assessment of severity. Assessment of the severity of tricuspid and mitral obstruction from proximal effects is adequate for most purposes. Assessment of the significance of pulmonary stenosis by the character of the murmur and the degree of the right ventricular hypertrophy by electrocardiography usually is sufficient for purposes of following the patient. The severity of aortic stenosis is difficult to determine precisely by history, physical examination, or electrocardiographic criteria. The clinician depends more on echocardiography and catheterization in the assessment of the clinical physiology of aortic stenosis than for pulmonary stenosis.

The severity of obstruction is assessed commonly in the catheterization laboratory by measurement of the transvalvar pressure gradient. Most longitudinal natural history data and recommendations for therapeutic interventions are based on the transvalvar pressure gradients. These gradients are output-dependent. Under sedation, a high cardiac output state could exist that would cause an overestimate of severity; ventricular failure with a low cardiac output would cause an underestimate of the severity of obstruction by use of the transvalvar pressure gradient. Another potential problem with the use of the peak systolic ventricular to peak systolic arterial pressure difference is that—particularly with aortic valve stenosis—noninvasive gradient calculation from the Doppler formula (which measures an instantaneous gradient) will give a higher number. This is so because the peak instantaneous pressure gradient actually is higher than the peak-to-peak pressure gradient (see Chapter 47, Doppler Echocardiography). This difference leads to confusion when those inexperienced with Doppler measurements make clinical decisions based on these measurements. Grading of the severity of semilunar stenosis by hemodynamic measures also can be based upon calculation of the valve area as

discussed in Chapter 54, Cardiac Catheterization—Hemodynamic Measurements. Calculation of valve area is cumbersome and, in most pediatric cardiac catheterization laboratories, is infrequently performed. Cardiac output always should be measured when one is judging the severity of an obstructive lesion. If there is a question of interpretation of the transvalvar pressure gradient because of a low or high cardiac output, it is helpful to have a calculation of the valve area.

The severity of regurgitant lesions may be assessed clinically. Tricuspid and mitral valve regurgitation result in a large systolic flow from ventricle to atrium followed by an increased amount of forward flow across the regurgitant atrioventricular valve during diastole. The low-frequency mid-diastolic murmur that results is often referred to as a Carey Coombs murmur (see Table 10–43). If a diastolic flow rumble is not present, the atrioventricular valvular regurgitation is of mild severity. Assessment of the severity of atrioventricular valve regurgitation by cardiac catheterization can be useful. The height of the "v" (or, more correctly, "r" for "regurgitant") wave of the atrial pressure tracing depends on the ventricular contractility as well as the severity of regurgitation. The atrial mean pressure is elevated when severe atrioventricular valve regurgitation is present. Angiography can contribute to the assessment of the severity of atrioventricular valve regurgitation. With severe atrioventricular valve regurgitation, the atrium is dilated and pulsations synchronous with ventricular systole may be seen in the hepatic veins in tricuspid regurgitation or the pulmonary veins in mitral regurgitation.

Mild degrees of regurgitation may be caused by a catheter traversing the atrioventricular valve. Thus, the retrograde approach generally is preferred for quantifying mitral regurgitation. An injection without premature ventricular contractions is important because catheter-induced premature beats cause regurgitation during angiography. Echocardiography contributes to the assessment of severity of atrioventricular valve regurgitation. With severe regurgitation, the atrium is dilated and a regurgitant jet can be mapped by Doppler to the venous attachments of the atrium. A broad regurgitant jet can be identified by color Doppler or by a careful, pulsed Doppler mapping. The velocity of the regurgitant jet will be related to the pressure difference between the atrium and ventricle in systole. Therefore, very mild mitral regurgitation can be expected to have a high velocity; a high velocity does not relate to the severity of the regurgitation.

The more severe the aortic or pulmonary valve regurgitation, the longer the murmur will be. Usually, the semilunar valve regurgitation murmur does not become louder with more severe regurgitation, it just becomes longer. The clinical assessment of the severity of pulmonary valve regurgitation is based on evidence of volume overload of the right ventricle. Aortic regurgitation may be associated with a low-frequency diastolic murmur at the apex from the regurgitant jet of blood, causing vibration of the anterior leaflet of the mitral valve (the Austin Flint murmur). If there is no Austin Flint murmur, the aortic regurgitation is generally mild. Peripheral manifestations of diastolic runoff (such as Corrigan pulses and Quinke's capillary pulse, as discussed in Chapter 43, History and Physical Examination) identify aortic regurgitation as severe.

Echocardiographic criteria for severe aortic regurgitation are, for the most part, based on the amount of diastolic runoff (such as reversal of flow in the aorta and prominant pulsatility of the aorta) and do not offer a great deal more precision in assessment than what is available from a careful physical examination. The important echocardiographic questions in the assessment of the physiology of aortic regurgitation for the clinician are "How dilated is the left ventricle?" and "How well does the left ventricle contract?" Angiographic assessment of the severity of aortic regurgitation relies on how many cardiac cycles are required to clear dye from the left ventricle. Aortic regurgitant lesions of mild severity will clear dye from the left ventricle after aortic root injection within several heart beats. Increasingly severe regurgitation will take longer and longer to clear dye. There are several methods to calculate the regurgitant fraction (see Chapter 54, Cardiac Catheterization—Hemodynamic Measurements). The regurgitant volume can be calculated by taking the difference between the left ventricular angiographic output (ventricular volume calculated by planimetry of systolic and diastolic frames using Simpson's rule or the area-length method times the heart rate) and the pulmonary blood flow (from thermodilution method). However, the most important aspects in the surgical decisions on aortic regurgitation in childhood involve the progressive increase in left ventricular size and decrease in left ventricular contractility—and not the regurgitant fraction.

PRESENCE OF OTHER HEMODYNAMIC BURDENS

Shone's syndrome of multiple left heart obstruction includes obstruction in LV inflow, LV outflow, and aorta. Associated defects may either increase or decrease the apparent severity of regurgitant or obstructive lesions. The obstruction to pulmonary venous return in a case with anomalous pulmonary connection and pulmonary atresia (a frequent combination in right atrial isomerism, "asplenia") may not be apparent until after an aorticopulmonary shunt is performed to increase pulmonary blood flow. Lutembacher's syndrome is an atrial septal defect with mitral stenosis. The presence of an atrial septal defect minimizes the likelihood of left atrial hypertension developing and makes the obstruction at the mitral valve subtle clinically. Multiple levels of obstruction also can alter the clinical physiology of an obstructive lesion. For example, if there is tetralogy of Fallot with severe obstruction at the level of the pulmonary valve, a severe distal obstruction at the level of the branching of pulmonary arteries would be less apparent than would be the case after the defect is repaired and the pulmonary obstruction is relieved because of the low pulmonary blood flow preoperatively. The same phenomenon can occur with multiple sites of obstruction on the left side of the heart. Pulmonary valve stenosis with an intact ventricular septum, in contrast, can minimize a potential infundibular obstruction with the severe right ventricular hypertension "stenting" open a hypertrophic infundibulum. This phenomenon can create a severe, although usually transient, subpulmonic outflow tract obstruction after surgical or catheter treatment. The clinical physiology of a regurgitant lesion also is potentially greatly influenced by the presence of other lesions. Tricuspid regurgitation could be critical if there was right ventricular volume overload from pulmonary regurgitation or right ventricular pressure overload from pulmonary stenosis. The presence of an obstruction at the same site as the regurgitation also can affect the clinical physiology of a regurgitant lesion. Aortic stenosis and aortic regurgitation often occur together. The combined pressure and volume overload cause a greater hemodynamic

burden for the left ventricle and a greater myocardial blood flow demand/supply mismatch than is found with either lesion alone.

AGE OF THE PATIENT

The age of the patient is an important factor in the clinical physiology of obstructive lesions. Severe left-sided obstructive lesions in the newborn generally are associated with a dilated left ventricle without hypertrophy. The same severity of obstruction developing gradually in the older child results in left ventricular hypertrophy, usually with a normal-sized left ventricular cavity. The abrupt transition from a predominantly right ventricular systemic pump (fetal circulation) to the neonatal (predominantly left ventricular) systemic pump in the case of a left-sided obstruction is very different physiologically from the same obstruction developing later in life. The neonate's myocardium has functional differences from the myocardium of the adult or older child. This age-related functional difference may result in less reserve for the neonate to adapt to the abnormal hemodynamics caused by an obstructive or regurgitant lesion.

IMPAIRMENT OF MYOCARDIAL CONTRACTILITY

Acute development of severe obstruction or regurgitation is more likely to result in rapid deterioration of hemodynamic function and myocardial function than obstruction or regurgitation that develops gradually. With chronic obstruction or regurgitation, adaptations of the myocardium to normalize wall stress occur. Hypertrophy has the disadvantage of resulting in an increased amount of muscle that requires delivery of blood from the coronary circulation. An increase in the metabolic demand of the myocardium can accompany this. If there is severe diastolic ventricular pressure overload, myocardial blood flow (particularly to the subendocardial regions) can be deleteriously affected by a high intramyocardial pressure. Extremes of chronic pressure overload and chronic volume overload will lead to myocardial fibrosis and ventricular dysfunction. Myocardial ischemia is probably a major contributor to this process. Development of ventricular dysfunction will clearly change the functional importance and clinical findings of an obstructive or regurgitant lesion.

CHAPTER 77

Cor Triatriatum, Pulmonary Vein Obstruction, Supravalvar Mitral Stenosis, and Congenital Mitral Valve Disease

Janette F Strasburger

COR TRIATRIATUM

Cor triatriatum is thought to result from embryologic failure of the common pulmonary vein to become incorporated into the left atrium during the fifth week of embryonic development.[1] This results in a fibromuscular membrane that subdivides the left atrium into a venous portion, sometimes called the proximal chamber (since it is proximal to the site of obstruction), and a true left atrial portion, referred to as the distal chamber. In almost all cases the left atrial appendage is distal to the cor triatriatum membrane. The location of the fossa ovalis is variable, and atrial septal defects may be present in either the proximal or distal chamber.[2,3] In the typical form of cor triatriatum, the "windsock" funnel-shaped membrane is perforated by a single hole (90%) or less commonly, multiple fenestrations (10%). Cor triatriatum can occur with associated partial anomalous pulmonary venous connections, or it can involve only two pulmonary veins. Sometimes in this situation there are also atrial septal defects. Cor triatriatum is differentiated from supravalvar mitral ring by the fact that the membrane in supravalvar mitral ring is usually shelf-like and located just superior to the mitral annulus. Supravalvar mitral ring rarely occurs as an isolated defect.

Cor triatriatum is a rare congenital anomaly, occurring in 4% of patients with cardiac defects.[4] In one autopsy series, it occurred as an isolated defect in 7 of 20 patients, and in the remainder, was associated with other congenital anomalies.[2] The most common associated anomaly was patent ductus arteriosus in 17%, anomalous pulmonary venous connections 8.6%, left superior vena cava 8%, and ventricular septal defect 7%.[2,5] Cor triatriatum has also been reported in combination with coarctation of the aorta, sinus venosus atrial septal defect, tricuspid atresia, Shone's syndrome, atrioventricular canal defect, tetralogy of Fallot, congenital mitral regurgitation, and Ebstein's malformation.[1–8] The male/female ratio is 1.4:1.[2] Familial recurrences have not been cited. Often cor triatriatum occurs in association with defects that may obscure its recognition. A large membrane opening in the left atrium, decompression of the proximal chamber due to an atrial septal defect, and decreased pulmonary blood flow may all contribute to a delay in the diagnosis of cor triatriatum.[1]

Cor triatriatum usually presents during infancy with symptoms of failure to gain weight; diaphoresis, and recurrent respiratory infections. Its presentation is similar to that of mitral stenosis. Eighty-five percent of patients with cor triatriatum presented under 40 yr of age and 8 of 20 presented under 1 yr of age. Rarely, however, individuals have presented during adulthood with chest fullness, dyspnea on exertion, cough, hemoptysis, atrial fibrillation, or other signs of pulmonary venous hypertension.[7] The age at clinical presentation usually depends on the degree of obstruction to left atrial blood flow, and in the presence of associated left-to-right shunts or other cardiac defects.[1–3,7]

The chest roentgenogram in cor triatriatum usually shows redistribution of blood flow with increased pulmonary vascular markings suggestive of pulmonary venous congestion.[1,7] The heart size is normal or only mildly enlarged. The left atrial shadow is usually not prominent in radiographs of children. The electrocardiogram may be normal; however, right-axis deviation, right atrial or biatrial enlargement, and right ventricular hypertrophy are more commonly seen. Atrial fibrillation is less common in patients with cor triatriatum than with mitral stenosis, and this arrhythmia rarely occurs in children.

On physical examination, the precordium is quiet unless pul-

monary arterial pressure is elevated, when there may be a right ventricular lift. S1 is usually normal, without an opening snap. The pulmonary component to the second heart sound may be increased. A soft, grade I-II/VI diastolic or continuous murmur is often audible at the left upper sternal border. Although infants generally present with dyspnea, failure to thrive, and pulmonary infections, older patients sometimes present with syncope, hemoptysis, or right heart failure. In patients with left-to-right shunts due to partial anomalous venous connections or proximal atrial septal defects, the symptoms and findings on physical examination may be those of a large left-to-right shunt. The electrocardiographic and radiographic features in these patients are similar to those of other patients with cor triatriatum; however, on physical examination, the second heart sound is usually widely split.[1,2,7]

Two-dimensional echocardiography from the left parasternal long-axis and apical or subcostal views, demonstrates a nonmobile membrane traversing the left atrium.[9–11] It is usually adherent to the upper portion of the left atrial lateral wall, and may at times be attached to the atrial septum. The mitral valve is not attached to the membrane but may show diastolic fluttering because of diastolic turbulent left atrial flow. Care must be taken to trace the entrance of all four pulmonary veins, especially if surgery is to be carried out without catheterization. Location of the patent foramen ovale and atrial septal defects is possible using a combination of two-dimensional echocardiography and pulsed Doppler.[12] Transesophageal echocardiography has been useful in proving the diagnosis in adult patients with poor anterior thoracic windows; however, the technique requires introduction of a gastroscopic transducer and is rarely necessary in pediatric patients.[1,4,7,9,10]

Three types of cor triatriatum have been described: 1) a fibromuscular diaphragm with no external deformity, 2) an hourglass constriction of the left atrium, and 3) an elongated tubular accessory left atrial connection. The diaphragm is composed of thickened endocardial tissue and muscle fibers, and is the most common form. Neither of the other forms contains this diaphragm. Examination of the lungs generally reveals only mild pulmonary vascular changes consistent with pulmonary arterial and venous vasoconstriction. These changes include medial hypertrophy and extension of muscularity into small arteries.[2]

At catheterization, elevation in pulmonary artery pressure is usually present. Misleadingly normal capillary pulmonary wedge pressures have been reported,[1,11] although generally, the pulmonary capillary wedge pressure is elevated.[2] The levophase of a pulmonary artery injection in the cranially angulated anteroposterior projection usually demonstrates associated anomalous pulmonary venous connections and atrial septal defects when present. Entry of the distal chamber by the transseptal approach, or via a patent foramen ovale can allow careful probing for the presence of a gradient across the orifice of the left atrial membrane. If the orifice of the proximal chamber is small, acute compromise in cardiac output can occur. Injection in the distal chamber in the left atrium demonstrates the subdivided left atrium and the left atrial appendage. A left ventricular injection can be performed to rule out mitral valve anomalies and other associated cardiac defects. When multiple cardiac defects are present, the diagnosis of cor triatriatum must be suspected, since it is often missed at catheterization in this situation.[1,2,4,7]

Surgical management is the treatment of choice for cor triatriatum and usually involves excision of the intra-atrial membrane. Dilation of the membrane intraoperatively has been associated with recurrence of stenosis. Reported mortality for all ages of patients is approximately 16%, but may be as high 25 to 50% in the sick neonate with associated major cardiac defects. No significant late mortality has been reported from arrhythmias or other problems. Reversal of pulmonary hypertension usually occurs unless there is residual obstruction or other defects. Often the membrane can be excised through the atrial septum, although the operation does require cardiopulmonary bypass.[13,14]

SUPRAVALVAR STENOSING MITRAL RING

Supravalvar mitral ring, or supravalvar stenosing ring of the left atrium, is an uncommon congenital anomaly consisting of a shelf-like fibrous ridge, or connective tissue invagination of the left atrial wall overlying the mitral orifice and often attached to the mitral annulus circumferentially.[7] Although its embryologic development is not clearly understood, it may result from abnormal atrial septation or defective subdivision of the endocardial cushions during early development of the heart.[15] In 90% of cases, supravalvar mitral ring is associated with other cardiac defects, most commonly with the Shone's anomalad of subaortic stenosis, parachute mitral valve, coarctation of the aorta and sometimes ventricular septal defect. Other anomalies associated with supravalvar mitral ring include ventricular septal defect alone, mitral valve stenosis and shortened chordae tendineae, patent ductus arteriosus, double-outlet right ventricle, and complete atrioventricular canal defect. The clinical presentation of supravalvar mitral ring is similar to that of other left-sided cardiac obstructive lesions described in this chapter. Most patients are symptomatic before 2 yr of age.

A number of patients have had successful surgical management of this defect. The operation usually consists of dissection of tissue away from the annulus and the mitral valve and excision of the ridge. One report has described a nonconcentric supravalvar mitral ridge containing the left circumflex coronary artery, so that care must be taken to avoid injury of the coronary arterial system.[16] Preoperative evaluation of coronary artery distribution is probably indicated. The prognosis of supravalvar mitral ridge is generally dependent on the severity of associated cardiac anomalies.[15]

UNILATERAL PULMONARY VEIN STENOSIS OR ATRESIA

Unilateral pulmonary vein obstruction usually occurs as the result of complete or partial occlusion of the pulmonary vein orifice by a flap or valve of fibrous tissue. The obstruction may be discrete, or there may be diffuse pulmonary vein hypoplasia. Obstruction may involve one pulmonary vein. However, it is more common for two veins on one side to be involved. This defect is extremely rare, occurring in about 1 in 30,000 children evaluated for congenital heart disease.[17,18] Approximately 50% of cases are associated with congenital intracardiac defects.[19,20] Associated lesions include ventricular septal defect, transposition of the great arteries, and less commonly, mitral atresia, systemic or pulmonary artery anomalies, coarctation of the aorta, patent ductus arteriosus, atrial septal defect, tetralogy of Fallot, and tricuspid atresia. Pulmonary vein obstruction may also be present in total or partial anomalous pulmonary venous connection, either congenitally or secondary to

surgical repair. Unilateral pulmonary vein obstruction appears to have an equal incidence of right and left pulmonary vein obstruction. However, with particular cardiovascular lesions, involvement of one side is predominant. For example, with ventricular septal defect, 75% of patients have had right-sided obstruction, whereas with transposition of the great arteries, all have had congenital left-sided obstruction. It has been postulated that the side of obstruction is related to preferential flow to the contralateral lung in these particular cardiac defects. In Driscoll and colleagues' review of 38 cases, seven involved stenosis of all four veins.[21] No sex predilection has been noted.[17,20–23]

Most cases of pulmonary vein obstruction are felt to be congenital because 1) there is a high incidence of associated congenital heart defects, 2) symptoms frequently develop early in life, 3) histology fails to suggest inflammation of the pulmonary vein orifices, 4) hypoplasia of the ipsilateral lung is also often present, and 5) similar types of obstruction occur with known forms of congenital heart disease such as anomalous pulmonary venous drainage. A number of acquired conditions can result in pulmonary vein obstruction as well, and these include obstruction due to atrial baffle procedures, pulmonary veno-occlusive disease, mediastinal tumor, mediastinitis, constrictive pericarditis, and extension of a left atrial myxoma or thrombus. In one case, unilateral pulmonary vein obstruction has been associated wth maternal Hashimoto's thyroiditis.[17,24]

The exact embryologic cause of pulmonary vein stenosis is not known. It is likely that this defect occurs relatively late in the formation of the heart, possibly after the common pulmonary vein is fully incorporated into the left atrium. In situations in which diffuse hypoplasia of the pulmonary vein has occurred, pulmonary flow was probably interrupted earlier, during the developmental period of pulmonary vein growth. It is also possible that destructive processes occurring within the left atrium during cardiac development could result in scarring of the pulmonary vein orifices.[19,23,25,26]

Unilateral pulmonary vein obstruction is generally well tolerated by the fetus, since bronchocollateral circulation vents the obstructed lung vessels. Bronchial-to-pulmonary anastomoses occur at the capillary, postcapillary, and precapillary levels and are capable of carrying up to 10% of postnatal pulmonary blood flow. Decreased flow in utero and postnatally through the pulmonary circulation, however, often results in hypoplasia of the ipsilateral lung.[25,26]

The severity of symptoms and the age of presentation with unilateral pulmonary vein obstruction depend on the severity of stenosis or atresia, associated cardiac defects, the degree of contralateral pulmonary blood flow and pressure, and the degree of ventilation/perfusion mismatching and atelectasis. Complete absence of symptoms has been reported with this defect. However, recurrent pulmonary infections and failure to gain weight may occur during infancy or childhood. Hemoptysis has been reported in older children.[19,22,23,27]

Physical findings include unilateral decrease in breath sounds on the involved side secondary to atelectasis and infection, mild cyanosis and clubbing, and chronic productive cough. Results of cardiovascular examination may be normal, but in cases in which pulmonary artery pressure is elevated, the P2 component of the second heart sound is increased, and there may be a right ventricular lift. Although ipsilateral pulmonary hypoplasia is often present, this is typically too subtle to detect on physical examination.[23,27]

The chest roentgenogram is helpful and often shows unilateral pneumonia or atelectasis. Pulmonary vascular markings on the obstructed side are normal or decreased, whereas the uninvolved lung demonstrates pulmonary edema with Kerley B-lines and pleural effusions, secondary to increased pulmonary blood flow. There is often hyperinflation of the normal lung and hypoplasia of the involved lung. The heart size is usually normal, but the pulmonary artery may be prominent.[27,28]

Technetium-99m lung perfusion scans often show markedly decreased or absent flow to the involved lung.[29] Normally, the left lung receives 45% of pulmonary flow, whereas the larger right lung receives 55%. Limited experience with two-dimensional echocardiography imaging suggests that it is not very sensitive in detecting unilateral pulmonary vein obstruction, although with improving resolution, and color-flow Doppler capabilities, it may be possible in the future to detect abnormal flow velocities, narrowing, or turbulence at the pulmonary vein orifices.

At cardiac catheterization the pulmonary artery pressure can range from normal to systemic.[28] Saturations in the involved artery may be high because of collateral blood flow. Left atrial saturation is decreased because of ventilation perfusion mismatching. Cineangiography often demonstrates preferential flow to the uninvolved lung. Because of increased flow, the contralateral pulmonary veins may be distended, but transit time is normal. Contrast may reflux from the pulmonary artery in the involved side and wash to and fro in the small pulmonary artery branches. Pulmonary artery wedge angiography is usually helpful in demonstrating pulmonary vein atresia or severe stenosis.[16] The pulmonary vein may not be visualized or may have a long delay in transpulmonary transit. On pulmonary artery wedge angiography, collateral bronchial vessels may fill, which communicate with the azygous system. Hemodynamic findings generally include elevated pulmonary artery and pulmonary capillary wedge pressures. Although unilateral elevation of the wedge pressure would be expected, there is often bilateral elevation secondary to pulmonary artery vasoconstriction.[20,27]

Surgery is usually most successful when discrete stenosis of the pulmonary vein orifice is present. It is often difficult to determine preoperatively whether pulmonary vein hypoplasia also accompanies this stenosis or atresia. Obstruction has been relieved by resection and dilation or patch enlargement of the orifice (Heineke–Mikulitz procedure for pulmonary venoplasty). In situations in which pulmonary venous drainage cannot be reestablished, these lung sections should be removed to prevent reflex vasconstriction secondary to ventilation perfusion mismatching.[26,27,30,31]

Results of balloon dilation angioplasty for pulmonary vein stenosis have not been promising.[19,21] Late recurrence of stenosis has been reported with relatively sudden recurrence of cyanosis 4 wk after dilation. One case of septic shock accompanied the procedure, possibly related to manipulation of infected pulmonary tissue. Although the results of surgery have not been optimal, an attempt at reestablishing pulmonary venous drainage is usually warranted in the patient with symptoms or hemodynamic abnormalities.

Mortality for the operative procedure is higher at a young age. The mean age at successful operation has been 8.8 yr. Many children continue to have abnormal flow distribution patterns by

lung perfusion scans postoperatively even when symptoms have been eliminated, supporting the concept that diffuse pulmonary venous hypoplasia usually exists.[21,27]

COMMON PULMONARY VEIN ATRESIA

Obstruction of the common pulmonary vein occurs when there is failure of anastomosis of the pulmonary venous confluence with the left atrium, or conversely, where this union regresses or becomes atretic. Unlike partial or unilateral pulmonary vein obstruction, this defect results in a blind common pulmonary venous pouch posterior to the left atrium. In addition, there is no connection to systemic venous channels, as seen in anomalous pulmonary venous connection. Embryologically, this condition probably develops late after regression of the venous channels connecting the splanchnic venous system of the lungs to the systemic venous system. If regression of these connections has not occurred, then total anomalous pulmonary venous connection would develop with drainage via the cardinal or umbilico-vitelline connections.[32,33] Bronchial veins become the only course of egress of pulmonary blood flow through the lungs in utero. Despite this fact, there is little development of bronchocollateral circulation. The development of bronchocollaterals is generally stimulated by the presence of precapillary obstruction, low oxygen tension, and low pulmonary pressures.[25] These are all conditions not found in common pulmonary vein atresia.

Common pulmonary vein obstruction is an extremely rare cardiac defect, with fewer than 20 reported cases. There appears to be no sex or racial predilection or familial occurrence. The defect is also usually not associated with other major cardiac defects.[32,34]

The clinical presentation of common pulmonary vein obstruction occurs early and is similar to that of obstructed total anomalous pulmonary venous connection. Most infants present in the first minutes to hours of life with severe respiratory distress, cyanosis, and grunting, and do not improve despite ventilation and 100% oxygen. The natural history is death within 1 mo.[32,33] On cardiac examination they have a hyperdynamic precordium with a right ventricular lift. S1 and S2 are loud and single and usually no murmur is present. The chest radiograph is similar to that of obstructed total anomalous pulmonary venous connection, or pulmonary lymphangiectasia with severe pulmonary venous congestion and little or no cardiomegaly.

At cardiac catheterization, the pulmonary artery pressure is usually systemic or suprasystemic with an increased pulmonary capillary wedge pressure. There is systemic desaturation. On angiography, contrast fails to opacify the venous bed and left atrium. Obstructed total anomalous pulmonary venous connection must be excluded.[33]

The only treatment for common pulmonary vein obstruction is surgical reanastomosis of the common pulmonary vein to the left atrium. Even with expeditous surgical treatment, no long-term survival has been reported to date.[33] This may be related to prenatal pulmonary vascular changes.

On gross pathology, the lungs are firm, edematous, and congested. The lymphatics are large and dilated within engorged intralobar tissue. Pulmonary veins are thick-walled and both pulmonary arteries and pulmonary veins demonstrate medial muscular hypertrophy.[32,34]

CONGENITAL MITRAL VALVE ABNORMALITIES

A number of congenital abnormalities of the mitral valve affect neonates and children. These include congenital mitral stenosis, congenital mitral insufficiency, cleft mitral valve, hypoplasia of the mitral valve and mitral valve annulus, anomalous mitral arcade, double orifice mitral valve, and mitral prolapse.

Embryologic development of the mitral valve is attributable to several sources. The mital valve leaflets develop from the left endocardial cushion tissue, and the papillary muscles and chordae tendineae result from undermining of the underlying ventricular muscle. The annulus of the mitral valve is part of the fibrous skeleton of the heart. The mitral valve apparatus is composed of the mitral annulus, the anterior and posterior mitral valve leaflets, separated by their commissures, the chordae tendineae, and the anteromedial and posterolateral left ventricular papillary muscles.[35] The mitral valve always accompanies the left ventricle, so that in ventricular inversion, the right-sided atrioventricular valve is most like the mitral valve. The anterior leaflet of the mitral valve is shorter at the base than the posterior leaflet but has a longer base-to-apex length than the posterior leaflet. Its arterial supply is from the left coronary artery. The posterior leaflet is C-shaped and covers the posterior two thirds of the mitral annulus. It receives its arterial supply from branches of both coronary arteries. The annulus of the mitral valve is composed of fibromuscular tissue and therefore contracts during atrial systole and throughout ventricular systole, allowing the mitral valve leaflets to overlap in the coapted position. There is fibrous continuity between the anterior leaflet of the mitral valve and the noncoronary cusp of the aortic valve. The chordae tendineae are cord-like branching collagenous fibers that attach the underside of the mitral valve to the left ventricular papillary muscle. The papillary muscles themselves are positioned within the ventricle anterolaterally and posteromedially. Occasionally, the heads of the papillary muscles may be split. Being muscular, the purpose of the papillary muscles is to tense the chordae tendineae and mitral valve leaflets during ventricular systole.[35,36]

Abnormalities in the development of the mitral valve apparatus can result in hemodynamic and physiologic alterations in blood flow. When alterations in left-sided cardiac flow occur early in fetal development, the mitral valve may be hypoplastic or even atretic, with an accompanying small left ventricular cavity. The spectrum of mitral atresia and severe mitral hypoplasia is discussed in Chapter 78 on hypoplastic left heart syndrome.

Congenital Mitral Stenosis

Congenital mitral stenosis occurs when anomalous development of the mitral valve results in physiologic and anatomic obstruction to blood flow from the left atrium to the left ventricle. Other congenital anomalies of the valve, such as double-orifice mitral valve or parachute mitral valve, can also cause obstruction to left ventricular inflow. In the adult, the normal mitral valve orifice area is 4 to 6 cm^2. An orifice of 2 cm^2 usually causes mild symptoms of mitral stenosis, and a 1-cm^2 orifice often causes severe symptoms. Normal values in children are dependent on body surface area.[35]

The age at presentation of mitral stenosis is usually dependent on the severity of mitral valve obstruction. Often older patients present with symptoms of dyspnea on exertion. Elevation in heart

rate usually results in proportionately greater shortening of cardiac diastole, limiting left ventricular filling. Exercise requires a greater cardiac output, and as a result of tachycardia, cardiac ouptut generally decreases with exercise in patients with mitral stenosis. With severe mitral stenosis, cardiac output may be reduced even at rest. The left ventricular volume is decreased and cardiac function is generally normal. Severe mitral valve stenosis may be associated with endocardial ischemia and fibroelastosis of the left ventricle. The left atrium is enlarged and there is secondary pulmonary venous hypertension. In general, the fetal bronchocollateral circulation is adequate to prevent prenatal cardiac failure from mitral stenosis. Infants with severe mitral stenosis generally present with dyspnea, respiratory distress, mild cyanosis, failure to grow, and recurrent respiratory infections. Their presentation is similar to that of cor triatriatum. Systemic output and perfusion may be low. Right ventricular failure may develop because of pulmonary hypertension and pulmonary arteriolar vasoconstriction. Typically with congenital mitral stenosis, there is a normal to decreased S1 and increased pulmonary component of the second heart sound. An S4 is sometimes audible due to enhanced atrial systole. There is usually a long pandiastolic murmur audible at the cardiac apex. The right ventricular impulse is often increased to palpation. Hemoptysis and recurrent respiratory infections may complicate the clinical course of older children. Atrial fibrillation is relatively uncommon in children, although the development of atrial arrhythmias can further compromise cardiac output and potentiate the risk of development of left atrial thrombi.[37]

The chest roentgenogram in congenital mitral stenosis usually shows left atrial enlargement and signs of pulmonary venous congestion. The redistribution of pulmonary blood flow may be seen in older children with increased flow to the upper lobes. Kerley B-lines and pulmonary edema may also be present. The electrocardiogram generally shows left atrial or biatrial enlargement in sinus rhythm. Atrial fibrillation may be present. There is generally right ventricular hypertrophy with right-axis deviation.[37]

Echocardiographically, the mitral valve apparatus is visualized from the apical and parasternal long- and short-axis views. The valve leaflets appear thickened and rolled. There is fibrous interchordal obliteration. Abnormal chordal insertions and decreased papillary muscle distance or fusion of papillary muscles may be present. The left ventricular volume is usually 70 to 100% of normal. The orifice area can be calculated both angiographically and echocardiographically.[38,39] Doppler echocardiography is useful in determining the flow velocities across the mitral valve. The normal transvalvular mitral flow velocity is 64 to 92 cm/sec.[38]

At cardiac catheterization, arterial blood gases may show systemic desaturation as a result of pulmonary edema. The left atrial pressure, pulmonary venous pressure, and pulmonary arterial pressures are usually elevated. There is a gradient between the left atrial A wave and the left ventricular end-diastolic pressure. The anatomy of the mitral valve is best defined in the right and left anterior oblique projections. Associated mitral regurgitation may be present on left ventricular injection. Congenital mitral valve stenosis is sometimes associated with coarctation of the aorta, subaortic stenosis, and left ventricular endocardial sclerosis.[37]

If left untreated, the mean survival for congenital mitral stenosis is 3 yr. The preferred treatment is open surgical commissurotomy, although balloon dilation, both intraoperatively and during catheterization, has recently been attempted for acquired mitral valve stenosis in adults. Closed commissurotomy is still performed in some countries.[37] The commissurotomy must be viewed as a palliative procedure, since symptoms often recur 5 to 10 yr after commissurotomy. This may be secondary to failure of growth of the annulus or to restenosis. The risk of increasingly severe mitral regurgitation is also present. In addition, in younger patients, the prognosis is dependent on the left ventricular volume and the severity of associated anomalies. The mortality rate for mitral commissurotomy is approximately 1 to 3%, and for mitral valve replacement, 5 to 8%. Surgery is generally indicated for severe mitral valve stenosis if medical management fails, in symptomatic women who wish to become pregnant, in patients with refractory arrhythmias and congestive heart failure, and in patients with thromboembolic phenomenon or severe pulmonary hypertension. Whenever possible, mitral valve replacement should be avoided in young children, since anticoagulation is necessary, and ultimate replacement of the valve is generally required.[40–42]

Mild to moderate mitral stenosis can be managed by diuretic therapy, supplemental nutrition, and aggressive management of respiratory infections. Usually digoxin is not helpful unless arrhythmias are present or there is left or right ventricular failure. In patients with atrial fibrillation, anticoagulation should be considered before cardioversion if the arrhythmia has persisted for more than 3 to 4 wk. In general, cardioversion is successful in children, and sinus rhythm can be maintained with digoxin alone or with digoxin and a class 1A drug such as quinidine or procainamide. Rarely, amiodarone therapy is necessary to maintain sinus rhythm. Patients with incessant atrial fibrillation should be maintained on anticoagulant therapy to prevent thromboembolic development.[35,40–42]

The pulmonary hypertension generally associated with mitral stenosis may resolve incompletely or very slowly after operation. This may be secondary to persistent vasoconstriction. Pulmonary vascular obstructive disease is rarely seen as the result of pulmonary venous hypertension.[40–42]

Parachute Mitral Valve

Parachute mitral valve exists when all chordae insert in a single papillary muscle or in fused papillary muscles. The chordae are generally shortened. This cardiac defect is associated with Shone's complex, including supravalvar stenosing mitral ring, subvalvar aortic stenosis, and coarctation of the aorta. Parachute mitral valve has also been seen with ventricular septal defect, atrioventricular canal defect, or right ventricular outflow-tract obstruction.

Age at clinical presentation of patients depends on the degree of left ventricular inflow obstruction, but usually occurs before 10 yr. Survival appears to be correlated most closely with left ventricular size. If mitral stenosis is severe, this defect is often difficult to manage surgically without mitral valve replacement.

Double-Orifice Mitral Valve

Double-orifice mitral valve is an unusual congenital anomaly that can be found as an incidental autopsy finding associated with ventricular septal defect, endocardial cushion defect, bicuspid aortic or pulmonary valve, or coarctation of the aorta, or less commonly, Ebstein's malformation, subaortic stenosis, and secundum atrial septal defect. Although mitral valve function is usually nor-

mal, both mitral stenosis and mitral insufficiency have been reported with double-orifice mitral valve. Unlike parachute mitral valve, in double-orifice mitral valve, two papillary muscles are present. Multiple small papillary muscles may also be present. Two-dimensional echocardiography can usually delineate three leaflets. The orifices are usually anterior and posterior. The defect must be differentiated from cleft mitral valve in endocardial cushion defect where the cleft mitral valve appears as a defect in the anterior leaflet resulting in a two-sided mitral valve structure. Thickening of the leaflets may be seen in double-orifice mitral valve when stenosis or insufficiency is present.[43]

Mitral Valve Insufficiency

In pediatric patients, mitral valve insufficiency, or regurgitation of left ventricular blood into the left atrium during ventricular systole, usually develops as the result of acquired conditions. Acquired mitral insufficiency can develop secondary to myocarditis, congestive or hypertrophic cardiopulmonary, bacterial endocarditis, coronary insufficiency secondary to myocardial infarction or papillary muscle infarction, connective-tissue diseases or storage diseases affecting the cardiac muscle, rupture of the chordae tendineae or papillary muscles, annular dilatation, chronic rheumatic heart disease, or after a number of operations that involve the mitral valve.[35,44]

During mitral regurgitation, the left ventricle decompresses into the left atrium. Half of the regurgitant volume during systole occurs before the opening of the aortic valve. When the regurgitant volume exceeds the stroke volume, cardiac output decreases in the base-line state. In the normal left ventricle, the ejection fraction or shortening fraction is usually increased; normal or decreased left ventricular function may imply left ventricular cardiomyopathy.[45] The left ventricular wall stress and tension are decreased in mitral regurgitation; therefore the oxygen consumption in the left ventricle is not significantly elevated.[35,44]

Clinically, symptoms of mitral insufficiency are dependent on the severity of regurgitation, associated cardiac defects, left ventricular function, pulmonary artery pressure, and the rate of development of the regurgitation. Acute mitral regurgitation of moderate to severe degree is usually poorly tolerated and leads to acute pulmonary edema and respiratory distress. This is usually due to acquired rupture of the chordae tendineae or destruction of the atrioventricular valve. Chronic mitral regurgitation often results in diaphoresis, recurrent respiratory symptoms and infections, exercise intolerance, tachypnea, and failure to grow due to high caloric requirements.[35,44]

On cardiovascular examination, there is usually a diffuse left ventricular lift with a palpably enlarged heart. S1 is normal or decreased, and the pulmonary component of the second heart sound is either normal or increased. Mitral regurgitation causes a blowing apical high-pitched pansystolic murmur, which must be differentiated by its location and radiation from the murmur of tricuspid insufficiency. The murmur of mitral regurgitation radiates into the axilla and may be associated with a low-pitched diastolic flow rumble or third heart sound.

The electrocardiogram usually shows left atrial enlargement and left ventricular hypertrophy. Atrial fibrillation is uncommon in children. Chest roentgenography shows enlargement of the left atrial shadow, splaying of the right and left bronchi, and generalized cardiomegaly with left ventricular enlargement. The pulmonary vascular markings are increased and pulmonary edema or Kerley B-lines may be present.

Abnormal mitral valve appearance, valve motion, and chordal attachments can be assessed by two-dimensional echocardiography. Systolic left ventricular function is usually normal or increased. The degree of mitral regurgitation can be qualitatively assessed by color-flow Doppler mapping. This is generally accomplished by determining the width of the regurgitant volume and the penetration into the left atrium, and is graded as mild, moderate, or severe. The left atrial pressure can be quantitated in the absence of distal stenosis, by computing the difference in the systemic blood pressure and the gradient across the mitral valve, as determined by the regurgitant flow velocity.[45]

At cardiac catheterization, the arterial blood gases are usually normal, although mild systemic and left atrial desaturation can accompany pulmonary edema. Pulmonary capillary wedge pressure and pulmonary arterial pressure are often mildly elevated, but rarely as high as that seen in mitral stenosis. It is important to enter the left atrium in order to rule out pulmonary vein obstruction. Injections in the left ventricle and the anteroposterior and lateral or right/left anteroposterior oblique angulated views are best for demonstrating the degree of mitral insufficiency.[44]

Mild to moderate insufficiency can generally be managed by diuretic or digoxin therapy. Afterload reduction has been lifesaving for acute mitral regurgitation. However, long-term use of agents such as captopril is currently under evaluation. Certainly, afterload reduction may be of some benefit in children with moderate to severe regurgitation.

Indications for surgical intervention include symptomatic mitral regurgitation that is poorly controlled by medical management. Worsening cardiomyopathy or the steady decrease in left ventricular contraction indices over time may also be an indication for mitral valve replacement. The surgical treatment of choice is valvuloplasty or annuloplasty, although frequently mitral valve replacement is necessary. The Carpentier ring is frequently used for annuloplasty.[36,41]

Mitral Valve Replacement

All mitral valve prostheses are smaller than the mitral valve annulus that they replace. Valves are currently available in sizes from 17 to 32 mm. The most common prosthetic valve used in the mitral position, is a low-profile tilting disk prosthetic valve such as the St. Jude's or Medtronic valve. These valves have a low thrombogenicity rate of approximately 2% per patient per year. They have a larger effective orifice and more rapid ventricular filling rates than previously available valves. The bioprosthetic porcine valves previously used have shown rapid rates of calcification in children. These valves are currently considered for use only in young women of childbearing age.[46–49]

Patients with prosthetic valves in the mitral position require anticoagulation. Initially heparinization is used during the first 2 days after operation. Generally, this is accomplished with low-dose heparin. Partial thromboplastin times are measured before administration of heparin, immediately after the loading dose and at regular intervals during administration. The partial thromboplastin time should be maintained at 1½ to 2 times the control level. Once oral feedings have been established and a stable diet

is maintained, warfarin (Coumadin) can be administered orally daily. Warfarin is monitored by prothrombin times. The dose is adjusted to maintain a prothrombin time between 1½ and 2 times the control value. The prothrombin time generally shows little change after 24 hr and a slow rise by the third day. Maintenance warfarin doses will generally range from 5 to 10 mg/day in an adult patient. It may be helpful to use a 5-to-6-day overlap period between heparin and oral warfarin and heparin.[50–52] Aspirin and dipyridamole (Persantine) are inadequate for anticoagulation. Prosthetic mitral valve thrombosis has been documented with this regimen in a child with a St. Jude's prosthesis. Anticoagulation is continued permanently.

St. Jude's tilting-disk valves are radiotranslucent, except when photographed on end.[53] Their proper function can often be assessed by a combination of auscultation, two-dimensional Doppler echocardiography, and M-mode echocardiography.[54–56] It is useful to have a base-line echocardiographic study in the early perioperative period. If fusion of the disk leaflet or perivalvular leak is suspected, cardiac fluoroscopy or cardiac catheterization may be useful. Extreme caution should be used when crossing a prosthetic valve that may be dysfunctional. Catheter entrapment has been reported.[46]

Young women of childbearing age require special consideration. The risk of thromboembolic phenomena during pregnancy necessitates anticoagulation for prosthetic valves. Even the use of subcutaneous heparin during the first 3 mo of gestation has been associated with an 8.3% thromboembolic rate. Many of these women, however, did not have newer types of valves. The risk of warfarin embryopathy was found to be 7.9% in patients in whom warfarin was not discontinued before the first trimester of pregnancy. Prophylactic insertion of a porcine mitral valve may be considered in a young woman requiring operation, but often the valve does not require replacement at this age, and the planning of pregnancy is somewhat unpredictable. The prosthetic porcine valve allows only a 3-to-5-year period for childbirth, and the progressive development of calcific mitral stenosis may actually increase the risk of pregnancy. Currently, subcutaneous heparin is used during the first trimester and for 3 wk before delivery in patients on anticoagulation who are in New York Heart Association Class 1. Patients are generally informed of the statistical risk of complications of pregnancy, and it is discouraged in patients who are in New York Heart Association Class 2 or worse.

CHAPTER 78

Hypoplastic Left Heart Syndrome

Gerald Barber

In 1952, Lev[1] first described the pathologic complex "hypoplasia of the aortic tract." This lesion included cases of: 1) isolated hypoplasia of the aorta, 2) hypoplasia of the aorta with ventricular septal defect, and 3) hypoplasia of the aorta with aortic stenosis or atresia with or without mitral stenosis or atresia. In 1958, Noonan and Nadas[2] referred to these lesions as "the hypoplastic left heart syndrome." While the pathologic complexes that result in the hypoplastic left heart syndrome are varied, the physiologic similarity of this collection of lesions has resulted in acceptance of this term. With the advent of surgical palliation for patients with hypoplastic left heart syndrome,[3–14] interest in a more precise anatomic definition of this collection of lesions has increased.

DEFINITION OF HYPOPLASTIC LEFT HEART SYNDROME

Hypoplastic left heart syndrome is a collective term describing a group of cardiac malformations in which there is aortic valve hypoplasia, stenosis, or atresia with either hypoplasia or absence of the left ventricle and, as a consequence, hypoplasia of the ascending aorta. This lesion is seen most frequently with severe mitral stenosis, mitral hypoplasia, or mitral atresia. The second most common association is with a common atrioventricular canal malaligned with regard to the muscular ventricular septum over the right ventricle. Cases involving transposition of the great arteries with hypoplasia of the left ventricle and pulmonary artery or hypoplasia of the right ventricle and aorta are not included in this group of malformations.

ANATOMY

Because hypoplastic left heart syndrome involves multiple pathologic entities, its anatomic manifestations are varied. Eighty-four percent of patients with hypoplastic left heart syndrome have aortic and mitral atresia, hypoplasia, or severe stenosis, while 16% have a malaligned atrioventricular canal.[15]

Aortic Atresia with Mitral Atresia

The anatomy of patients with aortic atresia (or virtual atresia) has been described thoroughly.[1,2,14,16–31] The inferior vena cava and right superior vena cava enter the right atrium normally. In 2.5 to 4.3% of patients there is a persistent left superior vena cava.[20,24] The right atrium is dilated (Fig. 78–1).[1,16–18,20,23,24] The tricuspid valve orifice is enlarged[15,23–25] with a mean circumference of 4.8 cm (normal circumference 3.4 cm).[23] The right ventricle is hypertrophied and enlarged.[17–19,23,24] In one study, right ventricular volume was three times normal.[23] The pulmonary orifice and main pulmonary artery are virtually always enlarged[15,17,18,20,23–25] and communicate with the descending aorta via the ductus arteriosus. Bharati[75] reported three cases of aortic atresia with pulmonary valve abnormalities (thickened nodular leaflets). Two of 126 cases of hypoplastic left heart syndrome presenting to the Children's Hospital of Philadelphia since 1985 have had concurrent pulmonic stenosis. The left and right pulmonary arteries arise from the underside of the main pulmonary arteries and may be larger than normal, normal in size, or smaller than normal.[25] In patients who die before reaching 2 weeks of age, there is no significant difference in the size and character of the small and medium-sized pulmonary artery branches.[14] In 2 out of 15 patients in this age

Fig. 78–1. Pathologic specimen from a child with hypoplastic left heart syndrome. The right atrium is dilated and the right ventricle hypertrophied. Severe endocardial fibroelastosis is present in the left ventricle (arrow). (Figure courtesy of P. Weinberg, MD.)

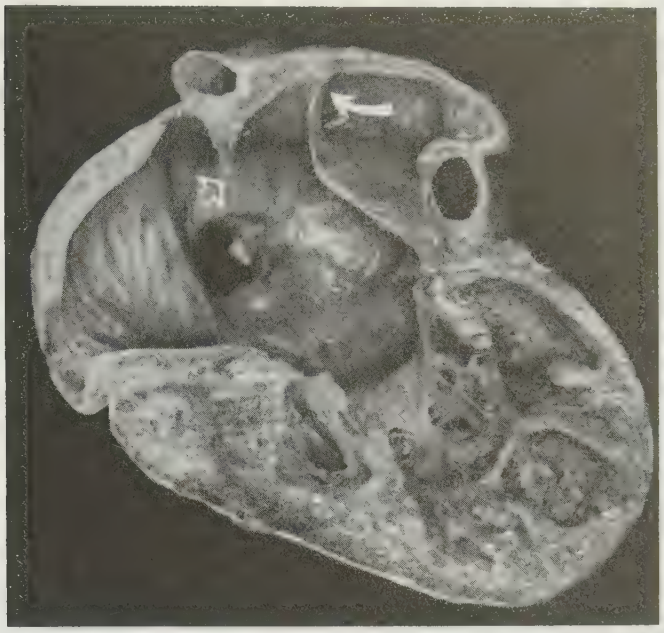

Fig. 78–2. Specimen from a child with hypoplastic left heart syndrome illustrating severe deviation of septum primum. The solid arrow points to the deviated attachment of septum primum from its normal attachment point (open arrow). Note how the gap between septum primum and septum secundum can be confused with a large unrestrictive atrial septal defect and how this arrangement in utero may limit systemic venous return to the left atrium. (Figure courtesy of P. Weinberg, MD.)

group and in all patients dying after 2 weeks of age studied by Sinha, there was medial hypertrophy of the pulmonary arteries.[14] Pulmonary venous connection is usually normal. Occasionally, there is anomalous or accessory pulmonary venous connection, usually through a persistent left vertical vein to a left innominate vein.[16] The left atrium is small and frequently hypertrophied.[16–18,20,23,24] An interatrial communication is usually present, although there may be a congenitally small foramen ovale.[16,17,24,27] In an autopsy series, 65% of patients had a posterior and leftward displacement of the superior attachment of septum primum relative to septum secundum (Fig. 78–2).[27]

Mitral stenosis or hypoplasia is present in approximately 60% of the cases while the remaining 40% have mitral atresia.[20,24] When there is mitral stenosis, the mitral valve leaflets are thickened with short thick chordae attached to short papillary muscles.[24] In cases with mitral atresia, there may be either a blind dimple on the floor of the left atrium at the usual site of the mitral valve with no grossly recognizable mitral valve tissue[17,18] or atretic mitral valve tissue.[30] The left ventricle does not form the apex of the heart. In cases with mitral hypoplasia or stenosis (patent left ventricular inflow), there is frequently prominent endocardial fibroelastosis (see Fig. 78–1)[1,14,20,22,24] with myofiber disarray,[31] focal calcification, and scarring of the myocardium. Evidence of early myocardial infarctions has been reported.[26]

In Bharati's study,[24] 87% of the patients with "hypoplastic left heart" had aortic atresia and 13% aortic stenosis while in Helton's study,[36] 61% had aortic atresia and 39% severe aortic stenosis. Of the 28 patients with aortic stenosis in Bharati's study,[24] 13 had a small bicuspid aortic valve, 7 had a small thickened tricuspid aortic valve that was normally divided, 2 had a small thickened incompletely divided tricuspid aortic valve, and 6 had a thickened unicuspid aortic valve. The coronary arteries originate normally from the aortic root and have a normal distribution.[24] The walls of the coronaries may be thicker than normal with multiple direct ventriculocoronary artery connections.[22] The clinical significance of these ventriculocoronary artery connections is as yet undetermined. The ascending and transverse aorta are hypoplastic. The typical figure of three contour of the upper descending aorta probably results from a juxtaductal ridge developing at a branch point of blood flow in the ductus arteriosus in utero.[32] With aortic atresia, the ascending aorta size is usually 1 to 3 mm. In rare cases with severe aortic stenosis, the mean ascending aorta size has been reported to be as large as 5 to 6 mm. Coarctation of the aorta is a common finding, which is present in 67 to 80% of the cases.[17,19,25,28,29]

Malaligned Atrioventricular Canal

The anatomic features of malaligned atrioventricular canal are similar to those of any atrioventricular canal defect. Atrial communication is via an ostium primum atrial septal defect. An inlet ventricular septal defect may or may not be present. The development of the left ventricle depends on the degreee of malalignment of the common atrioventricular valve. In cases with no or almost no inlet into the left ventricle (Fig. 78–3), left ventricular size is similar to that seen in patients with mitral atresia or stenosis. When part of the common atrioventricular valve enters the left ventricle, an intermediate size left ventricle is present. The left ventricle, however, still does not form the apex of the heart. Similarly, the size of the ascending and transverse aorta may be larger than in cases with aortic atresia but smaller than in patients with aortic stenosis.

Fig. 78–3. Short axis section through the heart of a child with a malaligned common atrioventricular canal. The small black arrows outline the common valve orifice while the larger black arrow points to the hypoplastic left ventricle. In this patient, none of the common valve emptied into the left ventricle. (Figure courtesy of P. Weinberg, MD.)

EMBRYOLOGY/ETIOLOGY

The embryologic cause of hypoplastic left heart syndrome is not known fully. Since hypoplastic left heart syndrome is a collection of lesions, there are probably multiple developmental anomalies that can lead to the syndrome. The most likely embryologic causes of hypoplastic left heart syndrome are either a limitation of left ventricular inflow or left ventricular outflow.

Left ventricular outflow obstruction may be the result of either severe aortic stenosis or atresia. When there is left ventricular outflow obstruction with an intact ventricular septum, the left ventricle is hypoplastic. In the rare case of left ventricular outflow obstruction with an unrestrictive ventricular septal defect, normal left ventricular development can occur. Thus, a primary myocardial abnormality is an unlikely cause of hypoplastic left heart syndrome. The resultant elevation in left ventricular pressure that occurs with patent left ventricular inflow (mitral stenosis) and obstructed left ventricular outflow in the absence of a ventricular septal defect probably causes the endocardiofibroelastosis seen in some cases of hypoplastic left heart syndrome. While a congenitally small or absent foramen ovale has been suggested as a possible cause of hypoplastic left heart syndrome,[24,46,47,48] this is more likely the result of increased left atrial pressure secondary to the left ventricular outflow obstruction. A primary abnormality of the aortic valve also might limit the development of the left ventricle in cases with a malaligned common atrioventricular canal. This may result in the atrioventricular valve appearing to be malaligned over the more normally developed right ventricle.

Theoretically, a displaced septum primum may limit left ventricular inflow by obstructing the normal shunting of inferior vena cava blood through the foramen ovale to the left ventricle. This decreased blood flow may result in a small left atrium, mitral valve, left ventricle, aortic valve, and ascending aorta. A displaced septum primum also may be present in some cases of hypoplastic left heart syndrome with malaligned common atrioventricular canal. Either this displacement of septum primum or the malalignment of the common atrioventricular valve may limit left ventricular inflow, resulting in a hypoplastic left ventricle, aortic valve and aortic arch.

Mitral stenosis, hypoplasia, or atresia is typically seen in hypoplastic left heart syndrome. Again, through limitation of left ventricular inflow, abnormalities of the mitral valve have been theorized as a primary cause of hypopoplastic left heart syndrome,[49–52] and experimentally a hypoplastic left ventricle can be produced in chick embryos by mechanical obstruction of the mitral valve.[53] Acquired mitral stenosis, however, frequently results in left atrial enlargement. Because patients with hypoplastic left heart syndrome have a hypoplastic rather than enlarged left atrium, congenital mitral stenosis probably is not a primary cause of hypoplastic left heart syndrome.

EPIDEMIOLOGY

Hypoplastic left heart syndrome has been reported to occur in at least 0.016% to 0.036% of live births.[37,38] In pathologic series, it represents 1.4 to 3.8% of congenital heart disease[39,40] and has been reported as causing 23% of the deaths due to the congenital heart disease in the newborn period.[16]

There is a slight male predominance in cases of hypoplastic left heart syndrome. Sixty to 70% of cases are reported to occur in males.[14,20,25] Currently, 57% of the patients with hypoplastic left heart syndrome seen at the Children's Hospital of Philadelphia are male. The recurrence risk for siblings of patients with hypoplastic left heart syndrome has been reported as 0.5% with a 2.2% risk for other forms of congenital heart disease.[37,41,42] Two genetic syndromes have been reported to have a high incidence of hypoplastic left heart syndrome. Three of 18 reported cases of duplication of the short arm of the twelfth chromosome had hypoplastic left heart syndrome[43] and Turner's syndrome has been detected in three patients with hypoplastic left heart syndrome seen at the Children's Hospital of Philadelphia.[44] Hypoplastic left heart syndrome has also been reported in one patient with a mosaic form of Turner's syndrome[45] and one patient with trisomy 18.[36] Single cases of hypoplastic left heart syndrome have been seen in patients with $4q^-$, $4p^-$, and $18p^-$ at the Children's Hospital of Philadelphia.

PHYSIOLOGY

Hypoplastic left heart syndrome patients have complex physiology. The left ventricle is essentially a nonfunctional structure. Pulmonary venous return must therefore pass to the right atrium. This occurs either through an atrial septal defect, a stretched foramen ovale or, rarely, by an anomalous pulmonary venous connection. In the right atrium, systemic and pulmonary venous return mix. The right ventricle must maintain both the pulmonary and systemic output, and the ductus arteriosus must remain patent for systemic perfusion. Perfusion is retrograde via the ductus arteriosus through the transverse arch and ascending aorta to the ca-

rotid and coronary arteries. With the left and right pulmonary arteries connected in parallel with the ductus arteriosus and descending aorta, the relative ratio of pulmonary to systemic blood flow depends on a delicate balance between pulmonary and systemic vascular resistances.

Prior to birth, oxygenation occurs via the placenta. Because the right ventricle is able to maintain systemic output via the ductus arteriosus, the child develops normally in utero.

After birth, oxygenation occurs in the lungs. Systemic blood flow is maintained as long as the ductus arteriosus remains patent. In the majority of cases, there is adequate systemic and pulmonary perfusion due to a balance between systemic and elevated pulmonary resistance. In some cases, however, there is a low pulmonary to systemic resistance ratio, resulting in excessive pulmonary blood flow. Although arterial oxygen saturation is elevated because of the high pulmonary blood flow, systemic perfusion is often marginal and the child frequently develops metabolic acidosis. In very rare cases, there is a high pulmonary-to-systemic resistance ratio. These patients appear markedly cyanotic because of inadequate pulmonary blood flow and acidotic because of inadequate oxygen delivery.

CLINICAL FEATURES

Historical Aspects

Because systemic perfusion and oxygenation are normal in utero, if the diagnosis is not made prior to birth by fetal echocardiography,[54,55] the child may be considered normal at birth.[2,16,17,26] Only 2 of 11 patients reported by Moodie[26] were in distress at birth; even so, distress was mild. When hypoplastic left heart syndrome presents within 24 hours of birth, it is usually because of severe obstruction to blood flow at the interatrial level (congenitally small or absent foramen ovale). More typically, however, Apgar scores are normal. Within 24 to 48 hours of birth, most patients with hyopoplastic left heart syndrome develop a dusky cyanosis with evidence of tachypnea and respiratory distress.[2,14,16,17,20] Watson,[16] however, reported that the onset of cyanosis and respiratory distress could be delayed for as long as 3 weeks. With ductal closure, the patient develops a metabolic acidosis. The mean pH at presentation prior to initiation of prostaglandins was 7.13 in one series[26] of 11 patients. Of 103 patients at the Children's Hospital of Philadelphia, the mean lowest preoperative pH was 7.22 ± 0.16 with a mean lowest preoperative bicarbonate concentration of 14 ± 5.5 mEq/L. Prostaglandin must be started at this stage to ensure patency of the ductus arteriosus if palliative surgery is to be considered. Both intravenous prostaglandin E_1 and oral prostaglandin E_2 have proven effective.[56–59]

Physical Examination

Physical examination typically reveals a mildy cyanotic child with tachypnea and tachycardia. Depending on the degree of ductal closure at the time of evaluation, peripheral pulses may be normal to diminished or absent. Watson[16] found diminished pulses in 32% of his patients whereas Sinha[14] reported diminished pulses in 60% of his patients. Rales may be heard, although generally the lung fields are clear. Cardiac examination reveals a dominant right ventricular impulse on palpation[16] with a decreased left ventricular (apical) impulse. S_1 is normal and S_2 is usually single and increased in intensity.[16] One-third of patients may have a gallop rhythm at the apex.[16] Fifty-eight to 67% of patients have a nonspecific soft grade 1/6 to 3/6 systolic murmur at the left sternal border[14,16,20] An apical middiastolic flow rumble is heard in 20% of the cases.[2,17] An early systolic ejection click may be heard in the rare patient with concurrent valvar pulmonic stenosis. Frequently, the liver is enlarged secondary to congestive heart failure.[16]

Electrocardiogram

The electrocardiogram (Fig. 78–4) frequently reflects the underlying pathology. Right atrial enlargement has been reported in 30 to 41%.[14,20] Watson[15] reported P waves that ranged from 0.5 to 4.0 mm with a mean of 2.5 mm in 27 patients. Two-thirds of his patients had a peaked P wave frontal plane. QRS axis is variable. Sinha[14] reported right axis deviation in 21 of 23 patients whereas Watson[16] reported a normal axis for age (mean +145 degrees) in 22 of 27 patients. Right ventricular hypertrophy is found in 78 to 92% of patients.[2,14,17] Approximately 56 percent of patients have a qR pattern in lead V_1 whereas 35% have either a rSR′ or pure R wave in lead V_1.[14,16] Q waves in the lateral precordial leads are seen in only 18% of patients.[16] Of patients, 36% are reported to have diminished left ventricular forces.[20]

In patients with malaligned common atrioventricular canal, the frontal plane QRS axis is leftward and superior.

Chest X-Ray

The chest x-ray in hypoplastic left heart syndrome (Fig. 78–5) is nonspecific. Cardiomegaly is reported in 75 to 85% of the patients.[14,20] In one series,[16] the cardiothoracic ratio varied from 0.54 to 0.68 with a mean cardiothoracic ratio of 0.62. The cardiac silhouette is described as globular (33%), rounded with a slight to moderate narrowing at the base (50%), or normal with a pulmonary artery bulge (17%).[16] Pulmonary vascular markings are increased in 68 to 82%.[14,20] In patients with a severely restrictive atrial septal defect, there may be a reticular pattern similar to that seen in total anomalous pulmonary venous connection with pulmonary venous obstruction.

Two-Dimensional and Doppler Echocardiography

Two-dimensional echocardiography is diagnostic in this lesion,[28,36,54,55,60–67] and its findings can have prognostic significance.[15]

All anatomic structures should be identified. Beginning with a transverse abdominal view, the inferior vena cava and abdominal aorta are identified and their relative positions noted. The hepatic veins and inferior vena cava should be followed to their entry into the right atrium. The intracardiac anatomy should be examined with subcostal frontal, sagittal, left oblique, and right oblique sweeps.[68–70] The relative sizes of the left and right atrium are recorded (Fig. 78–6). Pulmonary venous connection[71] should be established (Fig. 78–7). Because the pulmonary veins are usually enlarged due to pulmonary venous obstruction at the interatrial level, care must be taken not to confuse the pulmonary veins with the pulmonary arteries. Consistent with some obstruction at the interatrial level and an obligate atrial-level left-to-right shunt, the atrial septum is usually bowed from left to right. When the atrial septum is bowed from right to left, either severe tricuspid regurgitation or anomalous pulmonary venous connection should be suspected. When the atrial septum is thickened and severely bowed

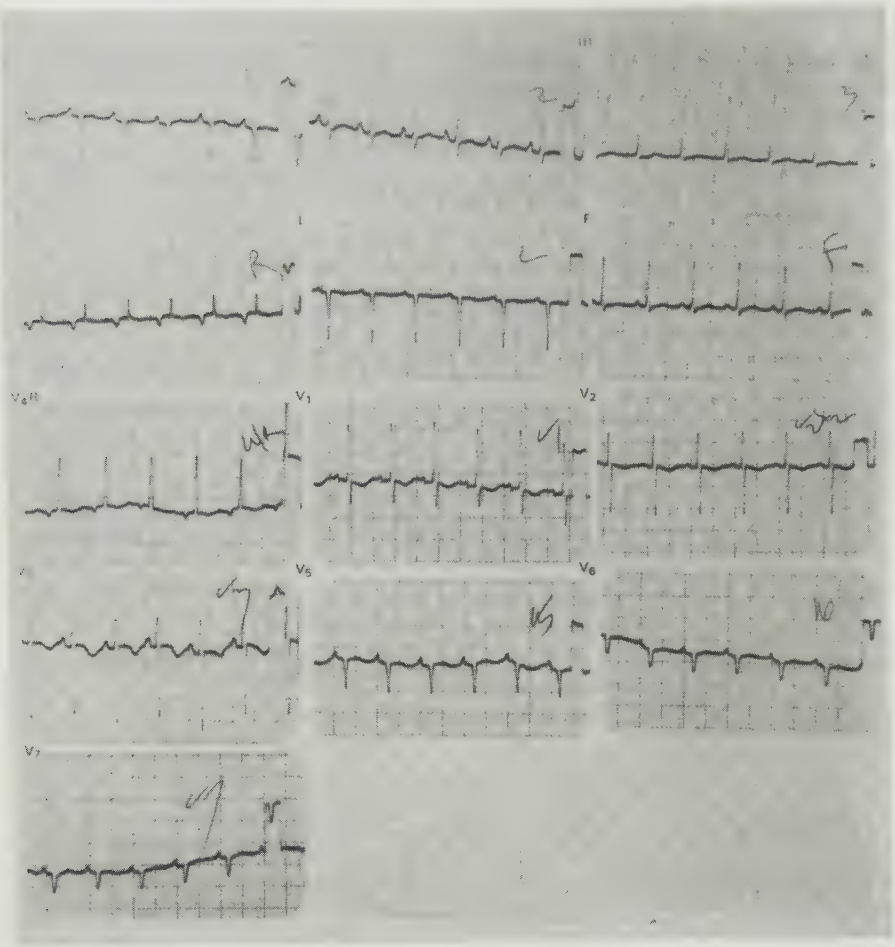

Fig. 78–4. Electrocardiogram in a child with hypoplastic left heart syndrome. "P" waves in lead II measure 2.5 mm. There are severe right axis deviation and right ventricular hypertrophy. Left ventricular forces are absent in leads V_5 through V_7.

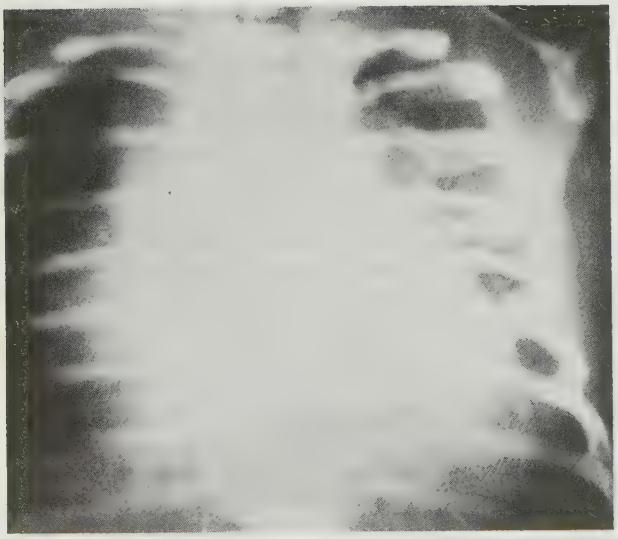

Fig. 78–5. Chest x-ray demonstrating cardiomegaly with increased pulmonary vascular markings in a child with hypoplastic left heart syndrome.

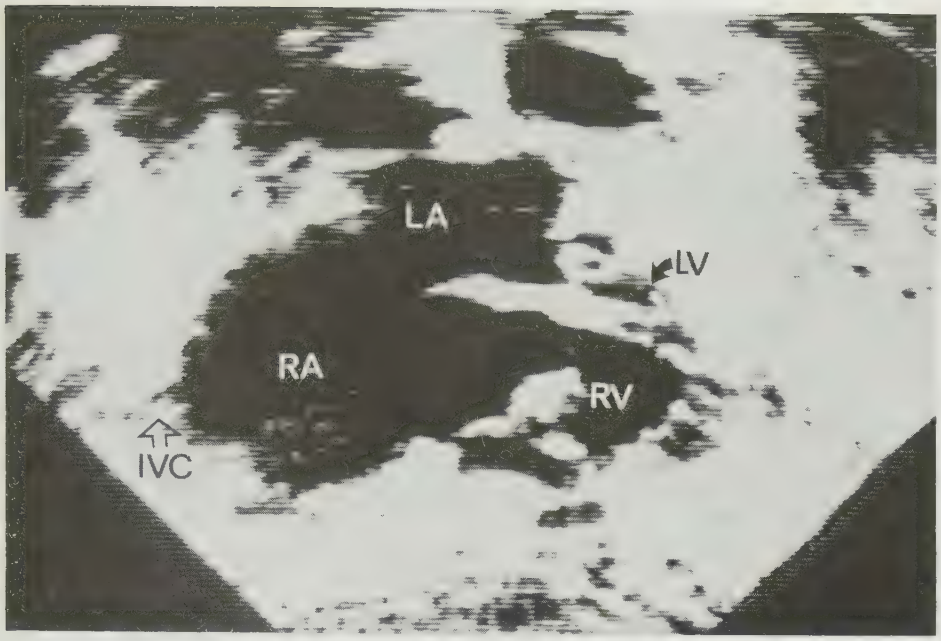

Fig. 78–6. Subcostal echocardiogram in a child with hypoplastic left heart syndrome illustrating the relative sizes of the left and right atria and ventricles. LA = left atrium, RA = right atrium, IVC = inferior vena cava, LV = left ventricle, RV = right ventricle.

from left to right (Fig. 78–8), a congenitally small or absent foramen ovale should be suspected. Septum primum should be examined for evidence of posterior and leftward deviation of its superior attachment.[36] In cases of mitral and aortic stenosis, the hypoplastic mitral valve, left ventricle and proximal ascending aorta should be characterized (Fig. 78–9). With mitral and aortic atresia, a left ventricle may not be visualized. The tricuspid valve (Fig. 78–10) should be evaluated for structural anomaly such as dysplasia or fusion and shortening of the chordae tendineae.[30] Right ventricular size and shortening can be assessed. The pulmonic valve should be evaluated for structural anomaly (Fig. 78–11). Following the right ventricular outflow tract, the ductus arteriosus and its connection with the descending aorta should be visualized.

In cases of malaligned common atrioventricular canal, an ostium primum atrial septal defect is visualized. The attachment of the common atrioventricular relative to the ventricular septum should be assessed (Fig. 78–12).

From suprasternal imaging, the anatomy of the ascending aorta, aortic arch, and upper descending aorta should be assessed using

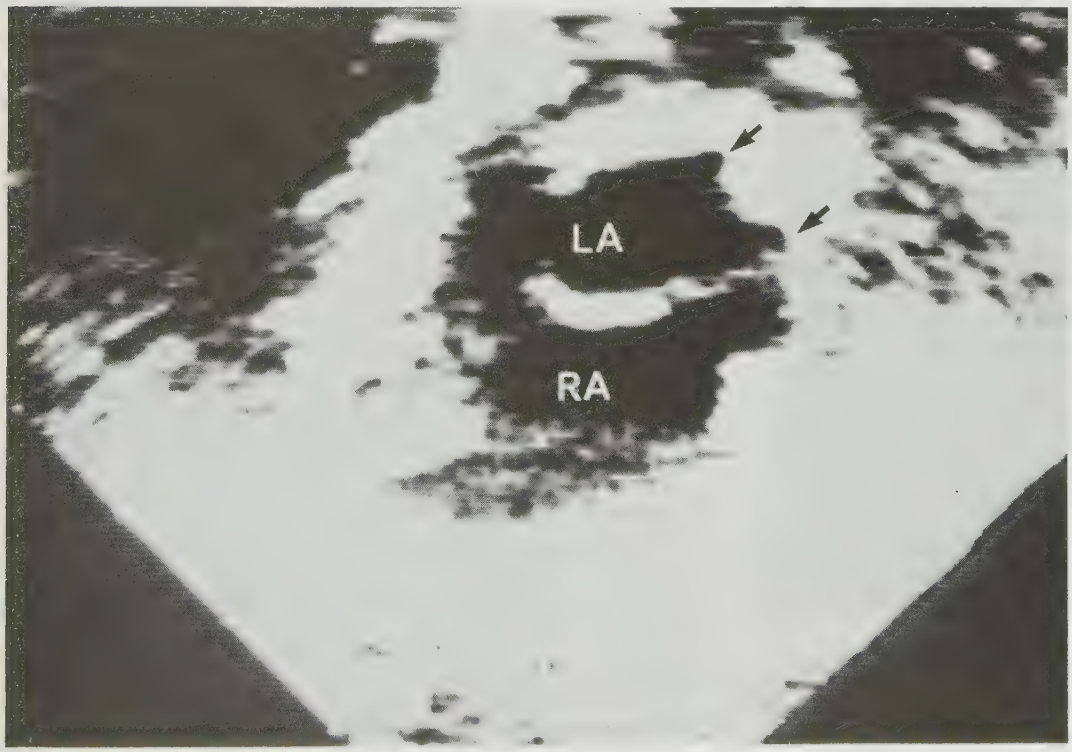

Fig. 78–7. Subcostal view demonstrating the entrance of the left pulmonary veins (arrows) into the left atrium. LA = left atrium, RA = right atrium.

Fig. 78–8. Subcostal view of a child with a congenitally absent foramen ovale. The left atrium is dilated. The atrial septum (arrow) is thickened and severely bowed from left to right. Blade/balloon septotomy was attempted after the left atrium was entered transseptally. Inadequate mixing at the atrial level persisted, and the child was operated on shortly thereafter. At operation, parts of the atrial septum measured greater than 1.0 cm. SVC = superior vena cava, LA = left atrium, RA = right atrium.

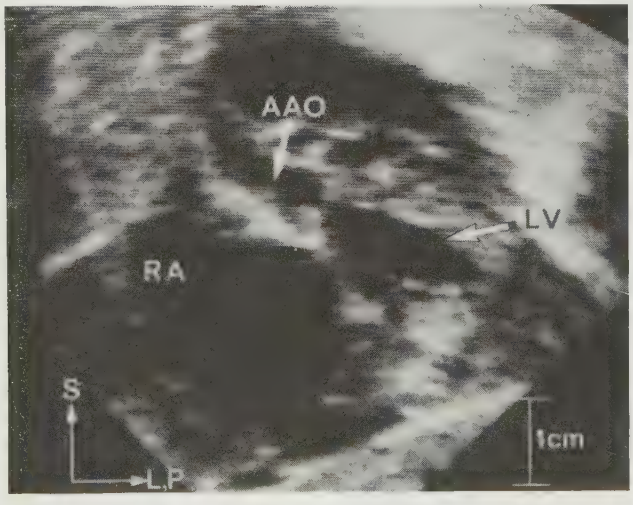

Fig. 78–9. Subcostal view demonstrating the hypoplastic ascending aorta arising from the small left ventricle. AAO = ascending aorta, RA = right atrium, LV = left ventricle, S = superior, L = left, P = posterior. (Figure courtesy of G. Helton, MD.)

frontal, sagittal, and left oblique views.[72] Continuity and size of the left and right pulmonary arteries are determined.

After the anatomic details are determined, color flow imaging, pulsed Doppler, and continuous wave Doppler are used to assess physiology. Of primary concern is the assessment of tricuspid or common atrioventricular valve regurgitation (Fig. 78–13).[15] Fifty-six percent of patients with hypoplastic left heart syndrome have tricuspid regurgitation preoperatively (35% mild, 16% moderate, and 5% severe).[15] The pulmonary valve then should be assessed to determine if there is any pulmonary stenosis.[75] If it is visualized, the mitral valve can be evaluated to determine whether it is stenotic or atretic. Similarly, the ascending aorta should be evaluated to determine whether the aortic valve is stenotic or atretic. The ductus arteriosus then should be evaluated to make sure it is not restrictive. The typical ductal flow pattern is a systolic flow from ductus to descending aorta with retrograde flow in the proximal descending aorta. During diastole, ductal flow is usually from aorta to pulmonary artery consistent with a lower pulmonary resistance than aortic resistance.[73] The absence of diastolic flow reversal into the ductus arteriosus suggests elevated pulmonary artery diastolic pressure usually due to a congenitally small or absent foramen ovale.

Cardiac Catheterization and Angiography

With accurate diagnosis possible by two-dimensional and Doppler echocardiography, cardiac catheterization is no longer routinely necessary in hypoplastic left heart syndrome.

Historically, cardiac catheterization has demonstrated superior vena cava oxygen saturations of 23 to 56%, right atrial saturations of 30 to 75%, with right ventricular and aortic saturations of 62 to 80%.[14] Mean left atrial pressure (25 mm Hg) is significantly

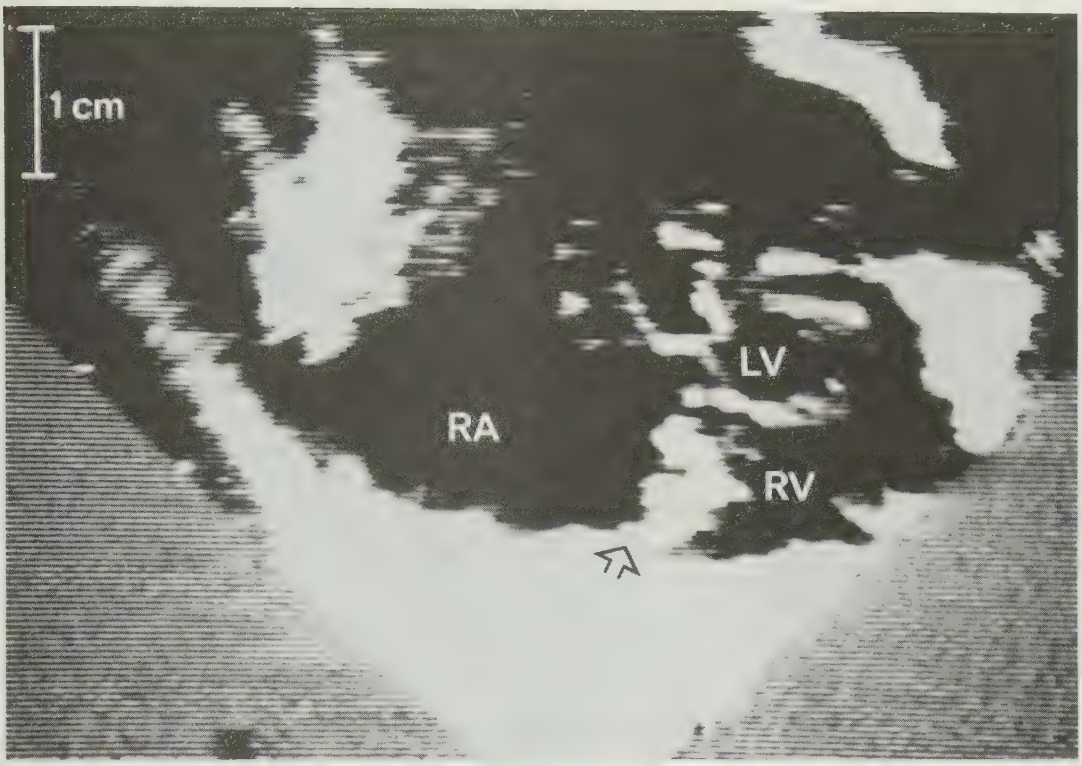

Fig. 78–10. Subcostal view demonstrating a thickened tricuspid valve (black arrow) in a child with hypoplastic left heart syndrome. The valve was bound down with short chordae and was severely regurgitant. RA = right atrium, LV = left ventricle, RV = right ventricle.

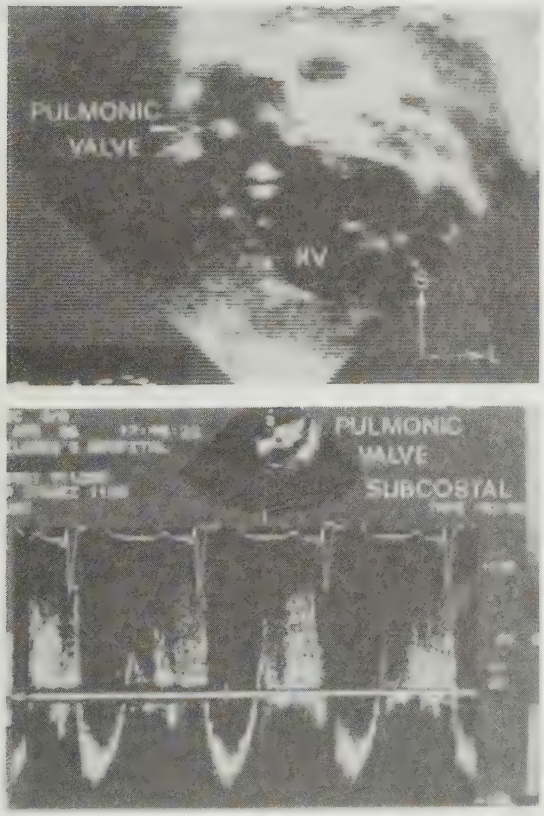

Fig. 78–11. Subcostal view of the right ventricular outflow tract and pulmonary valve (upper frame). The Doppler cursor is positioned below the pulmonary valve. In the lower frame, laminar systolic flow with turbulent diastolic regurgitant flow is demonstrated. RV = right ventricle, S = superior, L = left. (Figure courtesy of G. Helton, MD.)

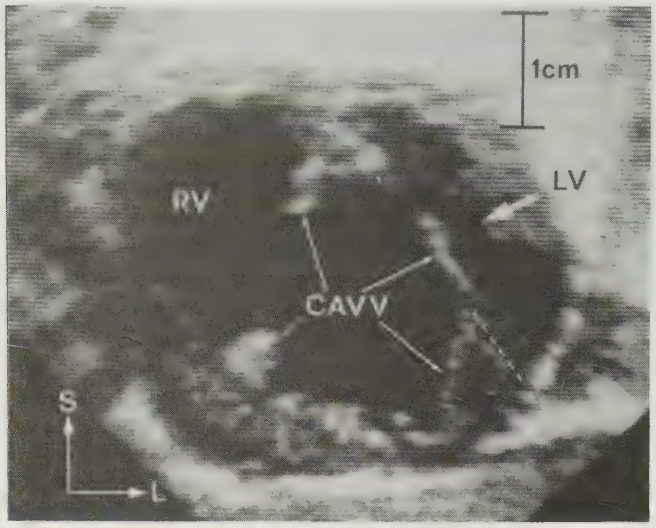

Fig. 78–12. Subcostal short axis in a patient with a hypoplastic left ventricle secondary to a malaligned common atrioventricular canal. The dotted line marks the plane of the ventricular septum. Arrows identify the orifice of the atrioventricular valve. The relative sizes of the right and left ventricles in this patient are illustrated. RV = right ventricle, LV = left ventricle, CAVV = common atrioventricular valve, S = superior, L = left. (Figure courtesy of G. Helton, MD.)

higher than mean right atrial pressure (12 mm Hg).[14] Right ventricular and pulmonary artery pressures are systemic.[14,20] Angiography on the right side (Fig. 78–14) of the heart reveals an enlarged right atrium, right ventricle and pulmonary artery.[17,20] The descending aorta is seen filling from the ductus arteriosus.[17] Injection in the descending aorta (Fig. 78–15) reveals the diminutive "string-like" ascending aorta.[16]

Hastreiter[76] attempted to validate catheterization measurements in hypoplastic left heart syndrome. In his study, he found that the right atrium was 1.6 times normal size, the tricuspid valve was 1.3 times normal size, the right ventricular diastolic volume was 1.8 times normal, the right ventricular systolic volume was 3.2 times normal, and the ascending aorta was 0.3 times normal size. While his autopsy measurements were uniformly smaller, presumably because of shrinkage, there was good correlation between angiography and autopsy measurements.

Because some obstruction to pulmonary venous return is beneficial by limiting pulmonary over circulation in patients with hypoplastic left heart syndrome, performing a balloon atrial septotomy during the cardiac catheterization may result in hemodynamic deterioration.

NATURAL HISTORY

The natural history of patients with hypoplastic left heart syndrome is uniformly poor. Untreated, over 95% of infants with hypoplastic left heart syndrome die within the first month of life.[77] Hypoplastic left heart syndrome accounts for approximately 25% of cardiac deaths during the first week and 15% of cardiac deaths during the first month of life.[2] Rarely, the ductus arteriosus remains patent. If pulmonary and systemic resistances are balanced, survival for 4 to 6 years has been reported sporadically.[13,78] One patient

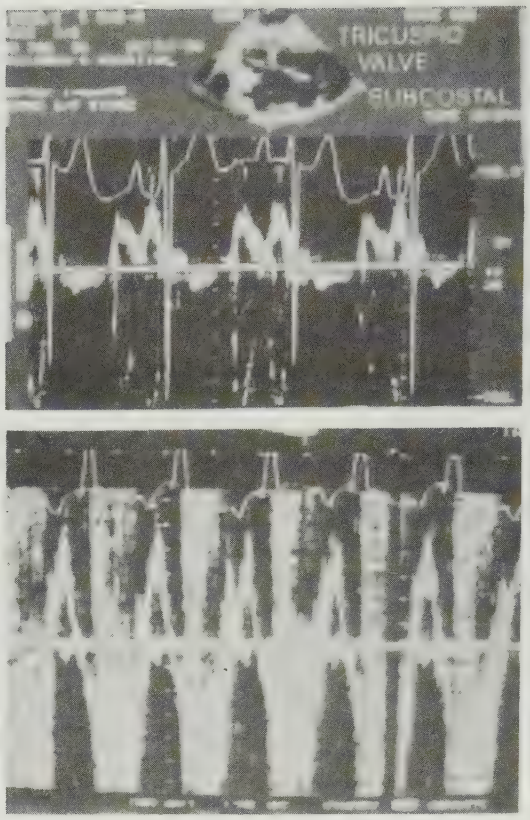

Fig. 78–13. Doppler signals obtained proximal to the tricuspid valve in hypoplastic left heart syndrome. The upper frame demonstrates normal laminar antegrade flow without evidence of tricuspid insufficiency. In the lower frame, there is turbulent systolic flow secondary to tricuspid insufficiency. (Figure courtesy of G. Helton, MD.)

at Texas Children's with pulmonary vascular disease survived to adolescence. These patients die from congestive heart failure, myocardial ischemia, and pulmonary vascular obstructive disease.

THERAPY

There is no medical treatment for hypoplastic left heart syndrome. The physician treating a patient with this disorder must decide whether or not to operate. Without surgery, survival is less than 5% at 1 year of age. With surgery, survival is 76% at 1 month and 61% at 1 year of age.[80] This survival rate is similar to that reported for surgery in other complicated forms of congenital heart disease such as pulmonary atresia with intact ventricular septum or truncus arteriosus. Historically, the surgical mortality for patients with pulmonary atresia with intact ventricular septum ranged from 20 to 65%.[81] Recently, early surgical mortality has been reported at 20 to 21%,[82,83] with late mortality of 21%.[82] In 1985, the Mayo Clinic reported their 15-year experience with truncus arteriosus;[84] surgical mortality there was 29%. Given the similarity of survival statistics between hypoplastic left heart syndrome, pulmonary atresia with intact ventricular septum and truncus arteriosus, the ethical issue of whether or not to operate also should be similar. Since most cardiologists and cardiovascular surgeons would not consider it ethical to withhold therapy from

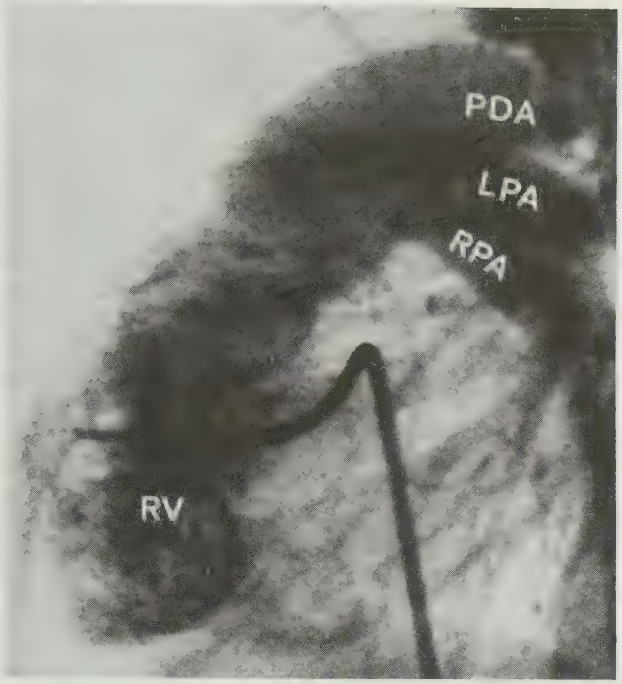

Fig. 78–14. Right ventricular angiogram in a child with hypoplastic left heart syndrome. Trabeculations consistent with a right ventricle are demonstrated. Both the left and right pulmonary artery and ductus arteriosus are visualized easily by the lateral projection. PDA = patent ductus arteriosus, LPA = left pulmonary artery, RPA = right pulmonary artery, RV = right ventricle.

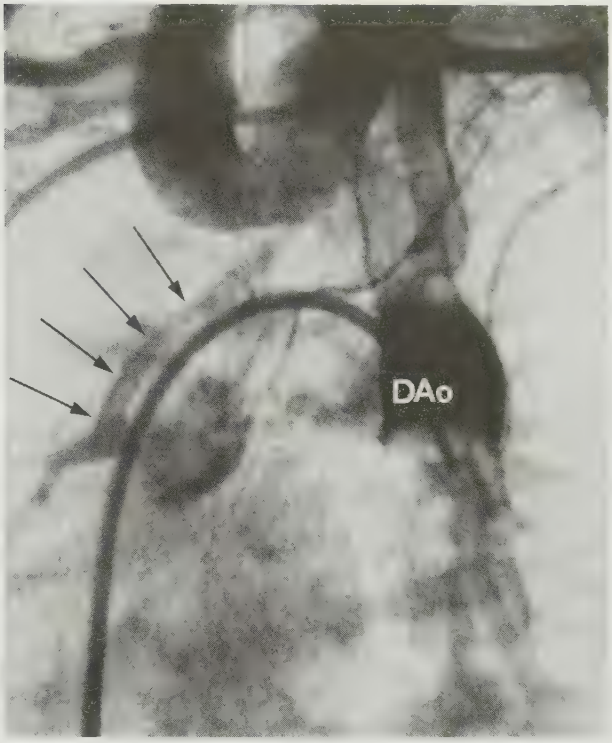

Fig. 78–15. Angiogram in a child with hypoplastic left heart syndrome demonstrating the hypoplastic ascending aorta (black arrows). The catheter is passed antegrade through the right ventricle, across the ductus arteriosus into the descending aorta. The descending aorta is balloon occluded and the injection made. DAo = descending aorta.

children with pulmonary atresia with intact ventricular septum and truncus arteriosus, it should be deemed equally unethical to withhold therapy from children with hypoplastic left heart syndrome.

Currently, there are two major surgical approaches for the hypoplastic left heart lesion. One operation involves reconstruction of the patient's own cardiovascular tissue in order to provide for hemodynamics compatible with life until a Fontan procedure can be performed whereas the second operation involves cardiac transplantation. The advantage of the reconstructive approach is the ability to use the patient's own tissue, thereby eliminating the need for immunosuppression; the advantage of the transplant is a two-ventricular repair.

Preoperative Care

The preoperative care of the child with hypoplastic left heart syndrome is the same regardless of the surgical approach chosen. When the diagnosis is made, the child should be started on prostaglandin E_1 intravenously at a dose of 0.05 to 0.10 micrograms/kilogram/minute. If available, orally administered prostaglandin E_2 may be used.[58,59] An arterial line should be inserted for monitoring of arterial oxygen saturation and acid–base status. If possible, the umbilical artery should be used to preserve the peripheral arteries for future use.

The major goal of the preoperative period is to assure adequate systemic perfusion for the child's metabolic needs. Systemic perfusion depends on a delicate balance between pulmonary and systemic vascular resistances. Usually the pulmonary resistance is less than systemic, and care must be taken not to further decrease pulmonary resistance. The chief metabolic factor that appears to influence pulmonary resistance in this group of patients is the P_{CO_2} level. For this reason, care must be taken not to hyperventilate these patients. Hyperoxic ventilation should be avoided. Patients with hypoplastic left heart syndrome often have no abnormality of oxygen transport across the alveolar membrane. The effect of supplemental oxygen is to decrease pulmonary resistance and increase systemic resistance, resulting in increased pulmonary blood flow and decreased systemic perfusion. While the oxygen saturation of peripheral blood may be higher, oxygen delivery is lower and metabolic acidosis ensues. Similarly, inotropic agents often result in an "unfavorable" pulmonary-to-systemic resistance ratio. While overall cardiac output may be increased, peripheral perfusion can decrease. Although they may be necessary in cases of hypoplastic left heart syndrome with additional problems such as sepsis, inotropic agents are usually unnecessary and harmful in uncomplicated cases of hypoplastic left heart syndrome. Once the pulmonary vascular resistance has decreased to a low level, it is often difficult to stabilize the systemic perfusion. One way to increase pulmonary resistance—and thus systemic perfusion—in these patients is to electively intubate and paralyze them. The child can then be hypoventilated to a P_{CO_2} of 45 to 50 mm Hg. This elevates pulmonary resistance and increases peripheral perfusion.

Some degree of pulmonary venous obstruction—usually at the level of a patent foramen ovale or atrial septal defect—is a frequent component of elevated pulmonary resistance in this lesion. Mild

to moderate interatrial obstruction benefits preoperative hemodynamics. Unless the P_{O_2} is less than 25 mm Hg, atrial septotomy should not be performed prior to surgical palliation.

In the rare case of hypoplastic left heart syndrome with a congenitally small or absent foramen ovale, there may be so much obstruction to pulmonary venous drainage that inadequate pulmonary blood flow results. In contrast to other patients with hypoplastic left heart syndrome, these patients have a low peripheral oxygen saturation. These patients also have no diastolic reversal in their ductus arteriosus on the preoperative Doppler echocardiogram. Such patients may require emergency surgery as it may be impossible to either stabilize them medically or to perform an adequate blade/balloon septotomy in the cardiac catheterization laboratory.

Neonatal problems must be recognized and treated. Since prostaglandin E_1 or E_2 can maintain patency of the ductus arteriosus, there is usually no need to rush a hemodynamically unstable child to the operating room. While it is logical to blame hemodynamic and metabolic abnormalities on the child's cardiac disease, sepsis always must be considered. In the presence of any evidence for sepsis, appropriate cultures should be performed and the child should be started on antibiotics pending culture results. The antibiotics chosen should be based on the sensitivities of organisms associated with neonatal sepsis in that institution. If the child is infected, surgery should be delayed until the infection is resolved. Renal and hepatic failure due to poor systemic perfusion should be recognized and treated. Necrotizing enterocolitis may occur due to decreased bowel wall perfusion.

Because of the association with Turner's syndrome, a karyotype should be obtained in all females with hypoplastic left heart syndrome. Due to the link between hypoplastic left heart syndrome and partial chromosomal deletions, a karyotype also should be obtained in males with any other somatic abnormality along with hypoplastic left heart syndrome.

Reconstructive Approach: First Stage

The first stage of the reconstructive approach for hypoplastic left heart syndrome (Fig. 78–16) is a surgical technique that uses native cardiovascular tissue to palliate this lesion. Since first described in 1980,[10] this technique has undergone many modifications. The goals of the first stage of the reconstructive approach are to assure systemic perfusion in the absence of a ductus arteriosus and to protect the pulmonary vascular bed for an ultimate modified Fontan[79] operation.

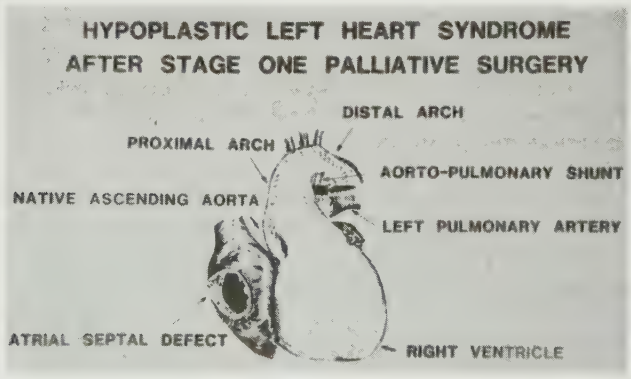

Fig. 78–16. Diagram of the first stage of the reconstructive approach for hypoplastic left heart syndrome. (Figure courtesy of W. Norwood, MD, as modified by G. Helton, MD.)

The first-stage palliative operation is initiated by induction of anesthesia with fentanyl and pancuronium. The radial artery is then cannulated. A midline sternotomy is performed and the thymus excised. After cannulation of the pulmonary artery distal to the sinuses of Valsalva and the right atrial appendage, cardiopulmonary bypass is begun. The infant is then cooled to 20° Celsius. The left and right pulmonary arteries are exposed and occluded with 2-0 Tevdek tourniquets. The brachiocephalic vessels are exposed and looped with 2-0 Tevdek tourniquets. The aortic arch is then dissected into the posterior mediastinum. The brachiocephalic vessels are occluded and circulatory arrest begun. After removal of the arterial and venous cannulae, cardioplegia solution is perfused through the pulmonary artery cannulation site. The descending thoracic aorta is then temporarily occluded and septum primum excised through the venous cannulation site. At the site of the takeoff of the right pulmonary artery, the pulmonary artery is transsected and the distal stump oversewn. A patch is used for this to avoid distortion of pulmonary artery anatomy. The ductus arteriosus is exposed and ligated. It is transsected at the aortic end. The aortic arch is then incised from 2 cm distal to the insertion of the ductus arteriosus to the level of the transsected pulmonary artery. The junction of the aortic isthmus is gusseted with a patch to minimize the development of late distal arch obstruction. A short, 4 mm shunt is then constructed from the underside of the augmented aortic arch to the branch pulmonary arteries. The pulmonary homograft is then carried around the aortic arch and the anastomosis finished by joining the proximal pulmonary artery and the pulmonary homograft with the ascending aorta. Cardiopulmonary bypass is reinstituted and the patient warmed. The patient is then weaned from cardiopulmonary bypass, a pressure monitoring line placed in the right atrium, and then transported to the intensive care unit.

Actuarial survival for this approach is currently 76% at 1 month and 61% at 12 months.[80] It is anticipated that with further identification of potential problems and refinement of techniques, the survival statistics will continue to improve.

Postoperative Management

Early

In the immediate postoperative period, therapy changes. Instead of hypoventilation to decrease pulmonary blood flow, the child should be hyperventilated to a P_{CO_2} between 20 and 30 mm Hg to decrease pulmonary vascular resistance. The child should be weaned from mechanical ventilation and extubated as soon as tolerated. Frequently, this takes 4 to 6 days.

Oral feeding should begin as soon as possible. Because children with hypoplastic left heart syndrome may not have been fed orally prior to surgery, sucking may be delayed. Oral intake may be supplemented by nasogastric gavage feeding. If the child is otherwise recovered from surgery, consideration should be given to teaching the parents the techniques of home gavage feeding.

Late

After the child is discharged, regular cardiovascular evaluations are essential for early detection of potential complications.

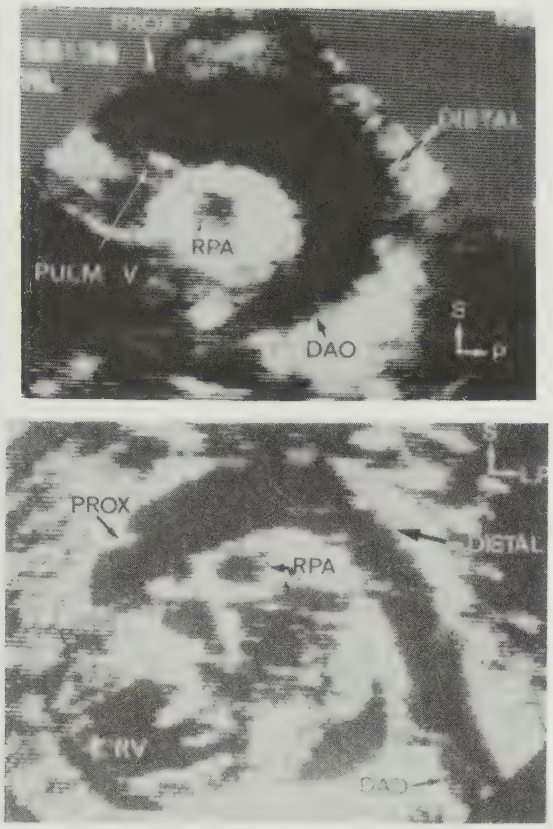

Fig. 78–17. Suprasternal (upper frame) and subcostal (lower frame) imaging of the reconstructed aortic arch in a child without postoperative arch obstruction. Prox = proximal anastomosis, Distal = distal anastomosis, Pulm V = pulmonary vein, RPA = right pulmonary artery, DAO = descending aorta, S = superior, P = posterior, L = left, RV = right ventricle. (Figure courtesy of G. Helton, MD.)

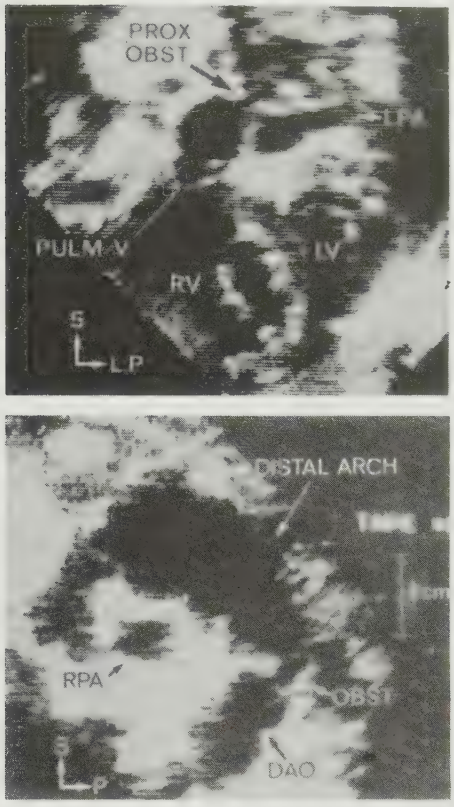

Fig. 78–18. The echocardiographic appearance of proximal and distal arch obstruction after palliation of hypoplastic left heart syndrome is apparent when the upper and lower frames of this figure are compared to those of Figure 78–17. Obst = site of obstruction, LPA = left pulmonary artery, LV = left ventricle. The other abbreviations are the same as for Figure 78–17. (Figure courtesy of G. Helton, MD.)

Aortic arch obstruction can occur at two sites: the commonest site is in the distal arch; the other is the proximal, threeway, anastomosis between the proximal main pulmonary artery, the homograft gusset, and the ascending aorta. While the incidence of arch obstruction has diminished, immediate recognition of it is critical for the child's well-being. In hypoplastic left heart syndrome after the first stage of the reconstructive approach, the right ventricle is volume loaded and pumps systemic pressure. Any concurrent extra pressure load results in rapid deterioration of right ventricular systolic performance. Physical examination is often misleading in the detection of arch obstruction. Because there is an obligatory run-of through the systemic-to-pulmonary shunt, the femoral pulses appear normal or nearly normal to palpation. Furthermore, the typical gradients are 25 mm Hg. It appears that the right ventricle usually decompensates long before a large pressure gradient is attained. Two-dimensional echocardiography with suprasternal imaging of the arch (Figs. 78–17 and 78–18) and sequential pulsed Doppler interrogation of multiple points (Figs. 78–19, 78–20, and 78–21) along the reconstructed aorta, however, has proven reliable in detecting arch obstruction after the first stage of the reconstructive approach.[85] Color Doppler has facilitated the assessment of the aortic reconstruction and allows more optimal alignment of the continuous wave Doppler cursor. If two-dimensional and Dopper echocardiography suggests arch obstruction, cardiac catheterization should be performed to confirm this and surgical relief undertaken without delay.

Another potential complication is the development of rapidly progressing cyanosis. Usually, this is due to limited perfusion through the shunt, although rarely cyanosis may occur secondary to an inadequate atrial septal defect (Fig. 78–22). While blade and balloon atrial septotomy have been attempted to increase the opening in the interatrial communication, they are rarely successful and a second surgical septectomy frequently is performed. Fortunately, this complication usually can be avoided by recognition of the variations of atrial septal morphology[36] and by performing an extensive initial surgical septectomy.

Tricuspid regurgitation can develop or persist. Significant tricuspid regurgitation is poorly tolerated by the already volume-loaded ventricle. Because of this and the fact that there is no significant change in the degree of tricuspid regurgitation from the preoperative period through the late postoperative period,[74] survival following the first stage of the reconstructive approach has been correlated to the degree of tricuspid regurgitation preoperatively.[15] Tricuspid annuloplasty or valve replacement may be required in cases with moderate to severe tricuspid regurgitation.

Mild regurgitation of the native pulmonary valve (neoaortic

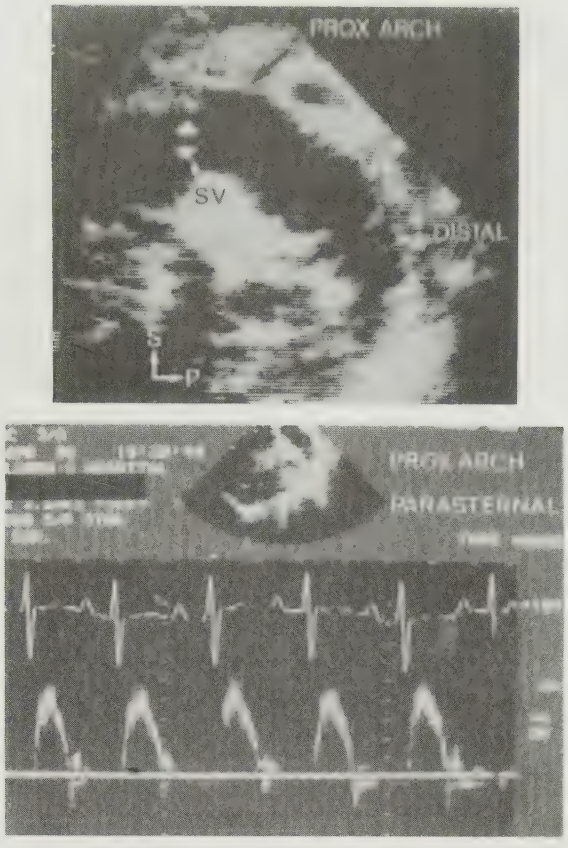

Fig. 78–19. Two-dimensional image (upper frame) and Doppler flow signal (lower frame) of the ascending aorta after first-stage palliation for hypoplastic left heart syndrome. Laminar antegrade flow without diastolic reversal is seen in the lower frame. SV = site of sample volume, Prox arch = proximal aortic arch, Distal = distal aortic arch, S = superior, P = posterior. (Figure courtesy of G. Helton, MD.)

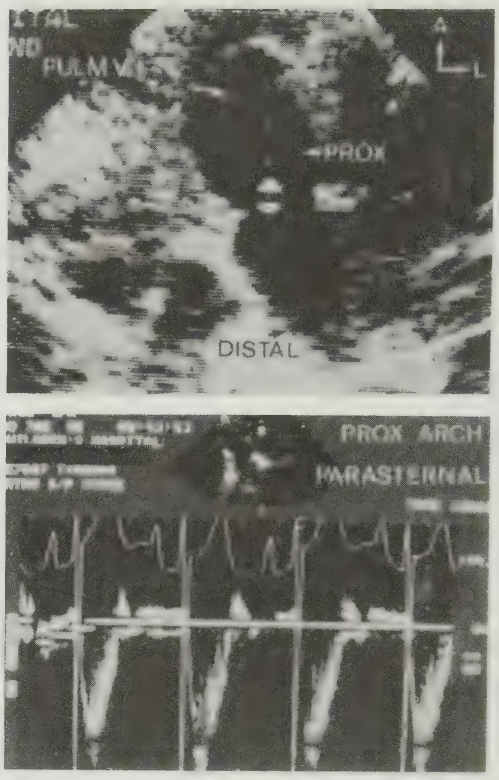

Fig. 78–20. The upper frame shows the position of the Doppler sample volume, which has now been moved to the site of the proximal anastomosis. Unobstructed laminar flow is seen in the lower frame. Pulm V = pulmonary vein, A = anterior, L = lateral, Prox = proximal anastomosis, Distal = distal anastomosis. (Figure courtesy of G. Helton, MD.)

valve) has been detected postoperatively by Doppler echocardiography but has not proven clinically significant.

In our early experience, evaluation by echocardiography (Figs. 78–23 and 78–24) occasionally revealed a disparity in the size of the left and right pulmonary arteries. In an effort to induce a more equal development of the pulmonary arteries and to allow for more favorable Fontan hemodynamics, the systemic-to-pulmonary shunt was changed from a modified right Blalock-Taussig shunt to a more centrally placed shunt. The relative sizes of the left and right pulmonary arteries should be assessed both echocardiographically and angiographically prior to the second stage of the reconstructive approach.

After the first stage reconstruction of hypoplastic left heart syndrome, the electrocardiogram remains relatively unchanged (Fig. 78–25). While the amplitude of the P-wave in lead II may decrease from the preoperative amplitude, typically right axis deviation with right ventricular hypertrophy and diminished R waves in the lateral precordial leads persists.

The chest x ray continues to show cardiomegaly after the first stage of the reconstructive approach for hypoplastic left heart syndrome. Pulmonary vascular markings are decreased relative to the preoperative chest roentgenogram.

Cardiac catheterization should be performed prior to the second stage of the reconstruction. The purpose of this catheterization is the same as in any pre-Fontan evaluation of a patient with single ventricle. Pulmonary resistance should be evaluated. Preferably, pulmonary artery pressure is measured directly with a catheter placed retrograde through the shunt. Occasionally the shunt cannot be entered. In these cases, pulmonary venous wedge pressures may be used. Right ventricular function is assessed by measurement of the end diastolic pressure. Usually, the right ventricular end diastolic pressure is about 7 to 8 mm Hg and the pulmonary artery resistance less than 2.5 Wood Units M^2. Routinely, two angiograms are performed. The first is a retrograde angiogram in the right ventricle filmed AP and lateral (Fig. 78–26). This defines ventricular morphology and demonstrates any tricuspid regurgitation that may be present. The second angiogram is in the midportion of the ascending aorta (Fig. 78–27). This angiogram is filmed AP with 30 degrees of cranial angulation and lateral. The cranial angulation is used to clarify the pulmonary artery anatomy. If the pulmonary arteries are entered through the shunt, a small volume injection is performed in the pulmonary arteries to define their anatomy.

Reconstructive Approach: Second Stage

The second stage of the reconstructive approach for hypoplastic left heart syndrome is a modified Fontan procedure.[79] In order to limit the amount of time the right ventricle is subjected to a volume

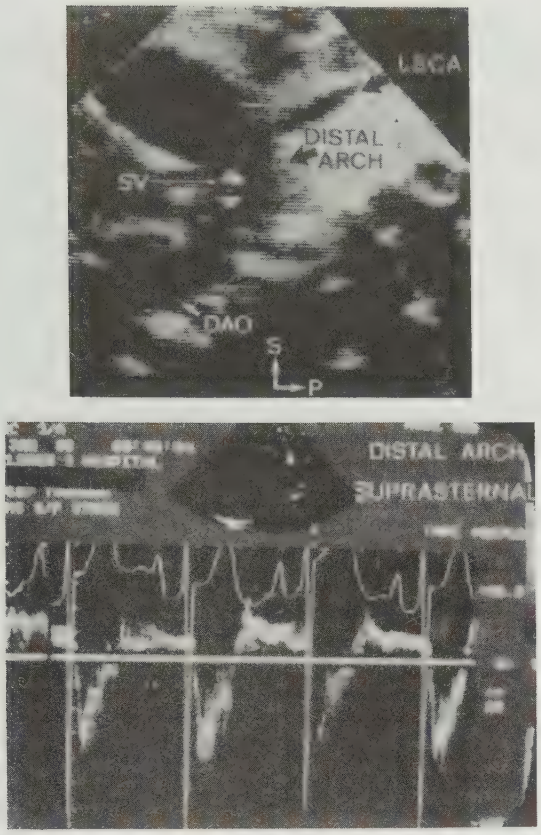

Fig. 78–21. The sample volume is now positioned at the site of the distal aortic anastomosis (upper frame). Laminar forward systolic flow with diastolic reversal into the systemic to pulmonary artery shunt is seen in the lower frame. SV = sample volume, LSCA = left subclavian artery, DAO = descending aorta, S = superior, P = posterior. (Figure courtesy of G. Helton, MD.)

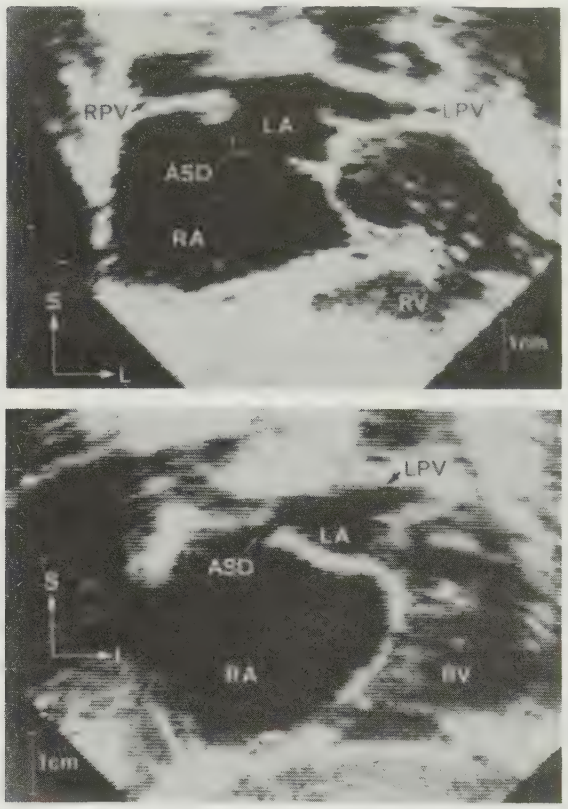

Fig. 78–22. Subcostal echocardiographic imaging in two children with hypoplastic left heart syndrome. A widely patent atrial septum is demonstrated in the upper frame. The lower frame demonstrates a restrictive atrial septal defect. The left pulmonary vein is dilated in the child with the restrictive ASD. RPV = right pulmonary vein, LPV = left pulmonary vein, LA = left atrium, ASD = atrial septal defect, RA = right atrium, RV = right ventricle, S = superior, L = left. (Figure courtesy of G. Helton, MD.)

and pressure load, this operation is performed at approximately 18 months of age.

The heart is exposed through a midline sternotomy and cardiopulmonary bypass begun through ascending aorta and right atrial appendage cannulation sites. The systemic to pulmonary shunt is exposed and occluded and the patient cooled to 20° Celsius. The aorta is then cross-clamped, cardioplegia infused, and circulatory arrest begun. The pulmonary arteries are widely incised from the right superior vena cava to the takeoff of the left lower lobe branch. The right atrium is then incised from the sulcus terminalis to the insertion of the eustachian valve inferiorly. The interatrial communication is enlarged, if possible, and an incision is made in the dome of the right atrium adjacent to the right pulmonary artery and carried into the posterior aspect of the right superior vena cava. A suture line is then begun at the posterior aspect of the right superior vena cava and the right pulmonary artery. Inferior vena cava blood flow is baffled from the inferior vena cava–right atrial junction to the junction of the superior vena cava with the pulmonary artery using half of a 10 mm diameter Gore-Tex tube. This baffling technique minimizes obstruction of the pulmonary venous channel, which occasionally occurred when the pulmonary veins were instead baffled to the tricuspid valve. The roof of the anastomosis between the systemic venous channel and the pulmonary arteries is then formed with a pulmonary homograft. The pulmonary homograft is extended along the remaining length of the pulmonary artery incision to ensure a widely patent communication into both the left and right pulmonary arteries. The patient is then returned to cardiopulmonary bypass, warmed, and weaned from bypass. Monitoring catheters are placed in the pulmonary artery and pulmonary venous channel, and the child is brought to the intensive care unit.

Postsurgical management is similar to that for any patient after a modified Fontan procedure. A follow-up cardiac catheterization is recommended 1 year postoperatively to assess hemodynamics.

Twenty-nine patients underwent the second stage of the reconstructive procedure for hypoplastic left heart syndrome from October 1984 through January 1987. Early mortality was 9/29 (31%) with 1 late death among the 20 survivors (7%).

Heart Transplantation

Yacoub first attempted heart transplantation for hypoplastic left heart syndrome in 1984. Shortly thereafter, Bailey[6] performed a baboon-to-human cardiac xenotransplantation for hypoplastic left heart syndrome. This child survived 20 days. In 1986, Bailey[5] reported his technique for orthotopic cardiac xenotransplantation for hypoplastic left heart syndrome. Although a baboon donor was

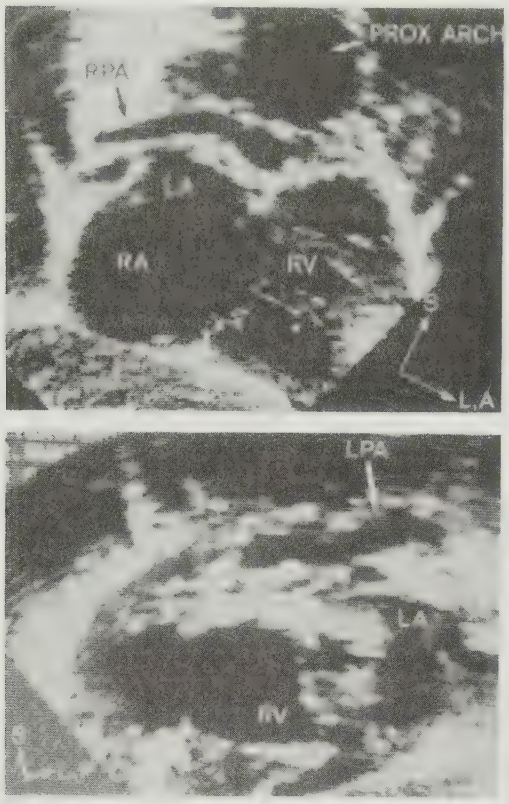

Fig. 78–23. Normal development of the right (upper frame) and left (lower frame) pulmonary arteries is seen in these subcostal images from a child with hypoplastic left heart syndrome after first-stage palliative repair. RPA = right pulmonary artery, LA = left atrium, RA = right atrium, RV = right ventricle, Prox arch = proximal arch, LPA = left pulmonary artery, S = superior, L = left, P = posterior, A = anterior. (Figure courtesy of G. Helton, MD.)

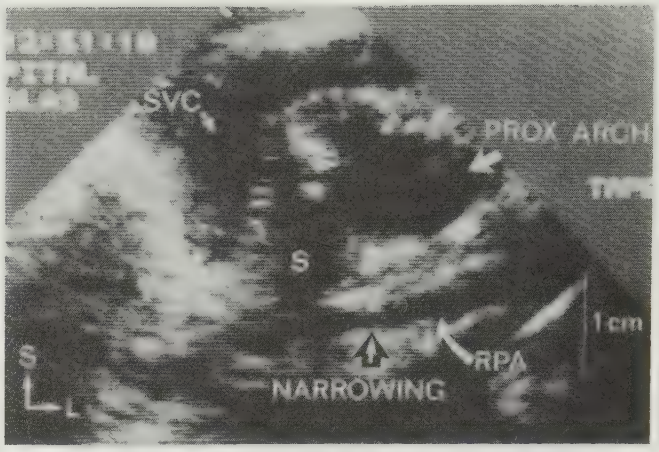

Fig. 78–24. Suprasternal two-dimensional echocardiogram demonstrating narrowing in the right pulmonary artery medial to a modified right Blalock-Taussig shunt. SVC = superior vena cava, Prox arch = proximal arch, S = shunt, RPA = right pulmonary artery. Superior and leftward directions are indicated by the direction arrows. (Figure courtesy of G. Helton, MD.)

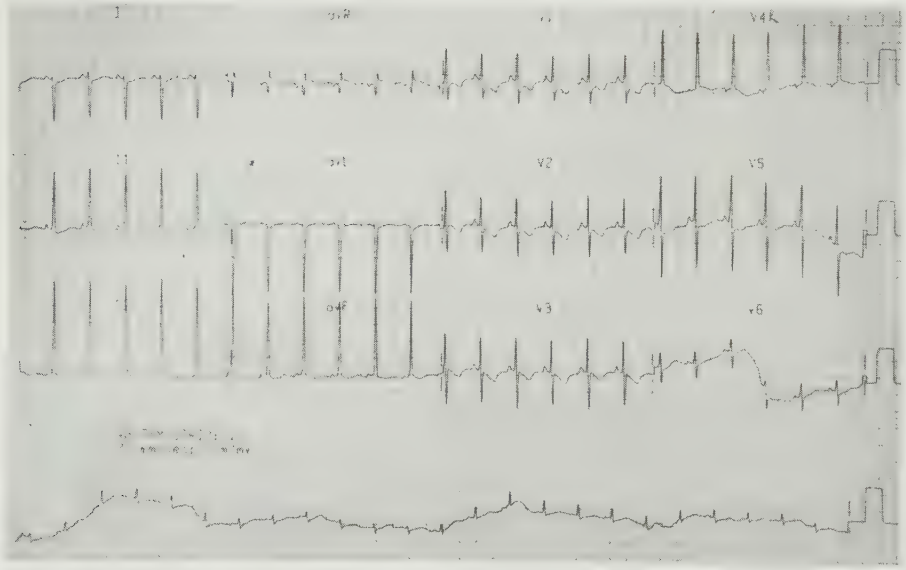

Fig. 78–25. Electrocardiogram obtained prior to the second-stage palliative operation for hypoplastic left heart syndrome. Right axis deviation and right ventricular hypertrophy are present. The R/S ratio in lead V_6 remains less than 1.

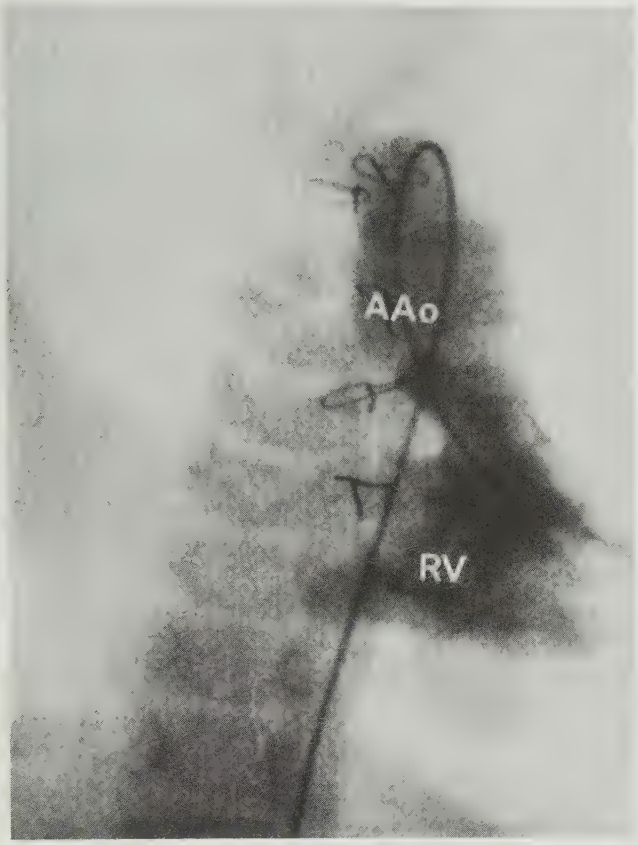

Fig. 78–26. Retrograde right ventricular angiogram after first-stage palliative repair of hypoplastic left heart syndrome. No tricuspid regurgitation is visualized. The ascending aorta anastomosis is widely patent. AAo = ascending aota, RV = right ventricle.

used, the donor source (allograft verus xenograft) should have no influence on the technical aspects of the operation.[6]

The child is anesthetized with a narcotic and paralyzing agent. Then heparin, methylprednisolone, and cefamandole are given, and surface cooling begun. The chest is opened with a midline sternotomy, and a near-total thymectomy is performed. Aortic arch branches are loosely snared. Extracorporeal perfusion is begun utilizing cannulation sites in the right atrium and ductus arteriosus. A snare is tightened around the ductal cannula, and the child is cooled to 20° Celsius. The arch vessel snares are tightened and bypass discontinued. The heart is then excised, leaving the posterior atrial walls and septum in place. The main pulmonary artery is transected at the bifurcation of the left and right pulmonary arteries. The ascending aorta is then ligated and transected just proximal to the brachiocephalic trunk. The ductus arteriosus is then removed from the underside of the descending aorta and the aorta incised from the brachiocephalic trunk to several millimeters beyond the ductus insertion site. The donor heart is inserted and sutured to the atrial remnant. Donor and recipient aortas are anastomosed, since the donor's aortic arch was beveled previously to match the incision in the recipient's arch. Donor and recipient pulmonary arteries are then anastomosed. Cardiopulmonary bypass is restarted. The child is warmed and weaned from bypass.

In 1986, Bailey[4] reported his results with cardiac allotransplantation for hypoplastic left heart syndrome. To date, 17 patients

Fig. 78–27. Retrograde angiogram in the ascending aorta after first-stage palliative repair. A right modified Blalock-Taussig shunt is visualized (arrow) with filling of the pulmonary arteries. Note the large size of the reconstructed ascending aorta after the first-stage reconstructive approach.

with hypoplastic left heart syndrome have been accepted into the transplant program at Loma Linda University Medical Center. Ten of these patients died awaiting a donor, and 2 died in the perioperative period. The 5 remaining children are doing well 3 to 18 months postoperatively.[86]

CONCLUSION

Over the last decade, well-defined surgical options have been developed for patients with hypoplastic left heart syndrome. The challenge for the future is to characterize this group of lesions better so that the preoperative, operative, and postoperative management may be further improved.

ACKNOWLEDGMENTS

The assistance of Drs. Norwood, Pigott and Bailey in the descriptions of the surgical techniques and of Drs. Norwood, Weinberg, Clark, and Chin in reviewing the manuscript is gratefully acknowledged.

CHAPTER 79

Aortic Stenosis: Valvular, Supravalvular, and Fibromuscular Subvalvular

Larry A Latson

Aortic stenosis is a term commonly used to describe any of several distinct lesions that cause obstruction to left ventricular outflow by an anatomic abnormality in proximity to the aortic valve. Detailed autopsy studies have shown that abnormalities of the aortic valve are probably the commonest of the congenital heart defects and may be seen in approximately 1% of the general population.[1] However, these bicuspid valves function well throughout childhood and often go undetected for many years. Thus, patients with such mildly deformed valves are not included in most clinical series on pediatric aortic stenosis. Children with bicuspid aortic valves should be detected as early as possible, however—even if the valves are functioning normally. There is a significant risk of bacterial endocarditis in these patients; they need appropriate counseling concerning antibiotic prophylaxis. In addition, we evaluate these patients clinically every 2 to 3 years since as many as 70% may develop some degree of either stenosis or insufficiency by age 30.[1,2] Calcification of these valves occurs commonly (but not invariably) after the third or fourth decade.

In this chapter, we will deal with the so-called fixed forms of aortic stenosis: aortic valvular stenosis, fibromuscular subvalvular aortic stenosis, and supravalvular aortic stenosis. As a group, these lesions usually are listed as the fourth or fifth most common form of congenital heart disease, occurring in 3 to 8% of patients with congenital cardiac malformations.[3-5] Although the physical findings and pathophysiologic effects of these lesions are similar enough that they are often grouped together, the epidemiology, natural history, and treatment varies significantly. Therefore, we will discuss each of these lesions separately.

AORTIC VALVULAR STENOSIS

Aortic valvular stenosis is the most frequent cause of "fixed" aortic stenosis; it occurs in 60 to 75% of patients with aortic stenosis in most series.[4,6,7] There is a definite sexual predilection, with aortic valve stenosis affecting males three to five times as often as females.[7-9] Associated congenital cardiac defects are seen in up to 20% of patients who have aortic valve stenosis as their major hemodynamic abnormality. The most commonly associated malformations are patent ductus arteriosus, coarctation of the aorta, and ventricular septal defect.[4,10]

Early descriptions of patients with aortic valve stenosis date as far back as the 1600s.[11] Prior to the early 1900s, most of the recognized cases of aortic valve stenosis were autopsy descriptions of calcific aortic stenosis in adults or critical aortic stenosis in young infants. It was not well appreciated until the early 1900s that the abnormal aortic valves seen in many older pediatric and young adult patients dying with calcific aortic stenosis were congenitally malformed.[11] It was, however, clearly recognized much before that time that aortic stenosis was a serious condition that often resulted in sudden death.[7,11,12]

Natural History of Untreated Forms

The "natural" history of patients with aortic valve stenosis is complex to ascertain because accurate diagnostic and surgical treatment techniques evolved at similar times.[7] Prior to the 1950s, the clinical diagnosis of aortic stenosis was uncertain (except in the most classic cases) and the degree of severity was difficult to assess. As better techniques for diagnosis and assessment of severity developed, patients with suspected severe stenosis often

were sent for surgical intervention and thus were not available for long-term follow-up of the "natural" history. The best possibility for studies on this subject are probably those involving patients diagnosed in the 1950s.[7,8,11]

Pediatric patients with aortic valve stenosis can be considered in two groups: 1) those with stenosis severe enough to lead to symptoms or definite diagnosis in infancy (usually prior to 1 year of age) and 2) those patients who are not initially diagnosed until at least 2 years of age. Approximately 10 to 15% of patients with aortic valve stenosis fall into the infantile group.[4,13,14] These patients usually have a more severe form of stenosis. Campbell estimated that 23% of patients with infantile aortic valve stenosis died in infancy when surgical intervention was unavailable.[7] In contrast, patients who survived the first year of life had a mortality rate of only 1.2% per year for the next two decades. Overall, the mean age of death in patients with valvular aortic stenosis was estimated to be 35 years with approximately 20% of patients dying in the first two decades of life. Although 60% of patients were alive at 30 years of age, 60% had died by 40 years of age. Many patients succumbed to progressive congestive heart failure, but over half died suddenly and unexpectedly.[7,11] The incidence of bacterial endocarditis was approximately 1% per year.

Anatomy and Embryology

The normal aortic valve is composed of three pocket-like cusps of approximately equal size with a semilunar shape to the free margins of the cusps. The cusps are normally smooth and pliable with a fibrous nodule—the nodulus Arantii—at the center of the free margin of each cusp.

In the embryo, the aortic valve is formed from three thick tubercles: two on the distal edge of the truncus swellings that septate the primitive truncus and a third from an intercalated valve swelling that appears opposite the two truncus swellings.[15] By the process of excavation, the swellings are transformed into the thin cusps of the valve and the sinuses of Valsalva. Formation of the aortic valve is virtually complete by 60 days of gestation.

The most frequent malformation of the aortic valve is the presence of only two cusps: the bicuspid aortic valve. In most cases, the leaflets of the bicuspid aortic valve are of unequal size and a raphe or false commissure is seen in one of the leaflets.[1,12] When the cusps are oriented toward the right and left, the raphe will usually be in the right cusp with the coronary arteries arising from behind each cusp. When the cusps are situated anteriorly and posteriorly, the raphe is usually in the anterior cusp, and both coronary arteries arise in front of the anterior cusp.[6] Because the free margins of a bicuspid valve are relatively straight rather than semicircular, mobility is limited. Although the majority of bicuspid aortic valves create minimal stenosis or no stenosis, thickening of the leaflets and partial fusion of the two leaflets can lead to severe stenosis even in the pediatric age group (Fig. 79–1).

Fusion of all three leaflets of the aortic valve leads to a unicuspid valve. This type of valve may have a central opening (with no true commissure) or may have a small eccentric slit-like opening extending to the annulus (making it unicommissural) (Fig. 79–1). In general, the fewer the number of cusps and commissures, the greater the likelihood that the valve is stenotic at birth.[6]

Uncommon causes of aortic stenosis at the valve level include myxoid dysplasia and annular hypoplasia. Valves with myxoid dysplasia may be tricuspid, but obstructive, because of the sheer bulk of the cusps. Myxoid dysplasia appears to be due to failure of transformation of embryonic myxoid tissue into the normal dense connective tissue of the valve.[16,17] In the rare patient with isolated hypoplasia of the aortic annulus, the aortic valve is usually only slightly abnormal.[6,18]

The left ventricle often shows secondary changes in infants with critical aortic stenosis. Mitral insufficiency is commonly found in association with pathologic evidence of papillary muscle infarction and fibrosis.[13,19] Endocardial fibroelastosis is seen in over 50% of infants who come to autopsy.[19,20] Left ventricular size can be increased or decreased.[21,22]

Etiology

The etiology of aortic valve stenosis is unknown. The pattern of occurrence in most families appears to be multifactorial. Recent

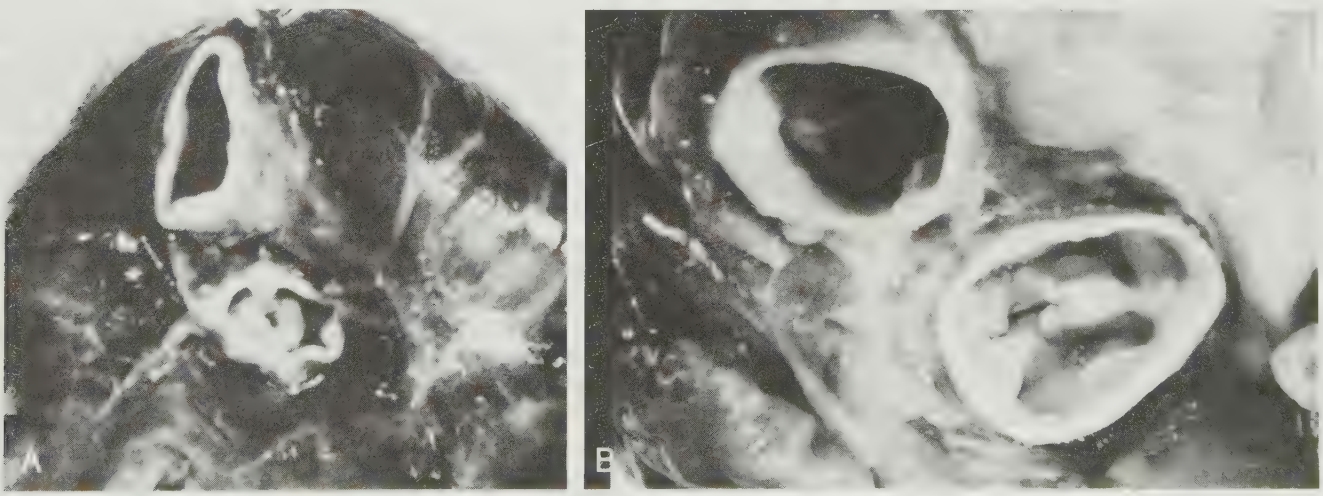

Fig. 79–1. Morphology of aortic valvular stenosis. (A) A unicuspid valve from a neonate with critical aortic stenosis is shown in the left panel. The aortic valve is markedly thickened, and there is only a small central orifice. The patient died suddenly 12 hours after apparently successful valvotomy. (B) Bicuspid aortic valve from a teenager is shown in the right panel. The leaflets are fused at the superior margins. Despite the markedly abnormal appearance, the valve was only mildly stenotic, and the patient died of unrelated causes.

studies have shown that the recurrence risk in the offspring of an affected father is only 3% whereas if the mother is affected, the recurrence risk is 13 to 18%. Mitochondrial cytopathy, vertical transmission of a slow virus, or other cytoplasmic (as opposed to chromosomal) abnormalities have been suggested as possible explanations for this difference.[23]

Abnormal fetal hemodynamics also may be related to the development of aortic valve stenosis and associated abnormalities. Premature closure of the foramen ovale has been associated with left heart hypoplasia.[24,25] Experimental interference with flow through the left AV valve in the chick embryo leads to varying degrees of left heart hypoplasia and aortic valve abnormalities.[26] Experimental obstruction to left ventricular outflow can induce hypoplasia of the left ventricle,[27] an associated finding in many patients who die of critical aortic stenosis in infancy.[20,21]

Physiology

Intrauterine adaptations of the circulation to even severe valvular aortic stenosis appear adequate to maintain normal growth and development of the fetus. In patients with critical stenosis, the fetal circulatory pattern is undoubtedly much like that in patients with hypoplastic left heart syndrome: The right ventricle supplies an increased proportion of systemic blood flow via the ductus arteriosus and left ventricular output is reduced. After birth, reduced pulmonary vascular resistance results in an increased volume of blood being delivered to the left ventricle. If the left ventricle is unable to fill and eject a normal volume of blood and the ductus constricts, systemic cardiac output no longer can be supported. Thus, patients with critical aortic stenosis who are dependent upon ductus flow may present abruptly with hypotension and shock at several days to weeks after birth when the ductus constricts. Infants who can maintain a reasonably normal cardiac output after ductal closure may have no symptoms or milder symptoms of congestive heart failure without circulatory collapse.

In all but the most severe forms of aortic stenosis, the resting cardiac output, heart rate, and mean systemic arterial pressure are normal.[28,29] To maintain this normal flow and systemic arterial pressure, left ventricular systolic pressure and, consequently, total work are elevated.[30] The increased systolic work in mature subjects results in hypertrophy sufficient to maintain wall stress at near normal levels.[31,32] In immature subjects, hyperplasia as well as hypertrophy may occur. Hyperplasia may explain why patients with congenital aortic stenosis show thickening of the left ventricle even as older children and adults.[33] The contractile state of the left ventricular myocardium in asymptomatic patients with aortic stenosis appears normal.[29,34]

A relative reduction in coronary blood supply to the hypertrophic left ventricle is one of the major hemodynamic derangements of severe aortic valvular stenosis. Subendocardial ischemia and infarction can be seen in patients with patent coronary arteries. Subendocardial coronary blood flow occurs predominantly in diastole. An estimate of the potential flow can be obtained by planimetry of the area between aortic and left ventricular pressure tracings from the dicrotic notch to the onset of ventricular systole. This area has been referred to as the diastolic pressure time index (DPTI).[35,36] Similarly, left ventricular oxygen requirement can be estimated by a systolic pressure time index (SPTI) defined as the area under the left ventricular pressure curve from the onset of systole to the dicrotic notch. The ratio of DPTI:SPTI has been used as an estimate of the supply:demand ratio of the left ventricle. This ratio (or variations of this ratio) has been useful in explaining ECG changes in some patients who apparently had less severe stenosis by other estimates of severity.[36,37] Coronary stenosis or obstruction can result in less coronary flow than would be predicted from the DPTI. Ischemic changes without a markedly abnormal DPTI:SPTI ratio should suggest this problem.[38] In patients without coronary disease, the major deficit of myocardial oxygen supply occurs in the subendocardial layers. This explains the pattern of distribution of primarily endocardial fibrosis in the left ventricle in infants dying with aortic stenosis.[37,39]

The demands of exercise present significant problems to patients with aortic valve stenosis. In order to increase cardiac output, there is usually a relatively large increase in heart rate and a variable increase or even decrease in stroke volume.[28,30] Standard hydraulic formulas indicate that the mean gradient across a stenotic valve is proportional to the square of the flow rate with each systole. Although stroke index increases only slightly, heart rate nearly doubles with maximal supine exercise. The tachycardia results in shortening of both the systolic ejection period and diastolic filling time.[40] The decreased systolic ejection period results in a faster ejection rate. Thus the peak systolic gradient increases (to a variable degree) with exercise in pediatric patients.[28] Diastolic filling period, the time during which flow occurs in the coronary arteries, is shortened even more than the systolic ejection period. Therefore, exercise-induced tachycardia in patients with severe valvular aortic stenosis results in decreased myocardial oxygen delivery at a time when systolic work is increased dramatically.[36]

The presence of baroreceptors in the left ventricle in dogs has been described.[41] Sudden increases in left ventricular pressure result in reflex vasodilation, primarily in the vascular bed of skeletal muscle. Although these baroreceptors are less well described in humans, it has been postulated that sudden activation of such baroreceptors by abrupt increases in left ventricular pressure in patients with aortic stenosis could lead to a fall in systemic arterial pressure with consequent reduction in coronary blood flow. This may be one mechanism for sudden death in aortic stenosis.[42]

Clinical Features

The majority of patients with congenital aortic stenosis are relatively asymptomatic in childhood, but approximately 10% present with signs and symptoms of congestive heart failure within the first year of life.[14] Symptoms are unusual in the first days of life. Two-thirds of patients with infantile aortic valvular stenosis develop symptoms by 2 months of age. A small number of these cases develop symptoms after 6 months of age.[13,14,43–45] Tachypnea, poor feeding, and growth failure may be prominent in infants with congestive heart failure. Hepatomegaly and peripheral edema may be evident. Patients presenting at less than 1 month of age present in a shock-like state with poor peripheral perfusion and frank cyanosis, similar to patients with the hypoplastic left heart syndrome.

In young infants, the most prominent physical findings with critical aortic stenosis may be a hyperactive precordium and poor pulses. In patients under 2 years of age, the precordial impulse often suggests right ventricular hyperactivity. Most infants with severe valvular aortic stenosis have at least a soft ejection murmur along the upper left sternal border radiating to the neck. The murmur may be very inconspicuous in younger patients with severe

failure. The typical murmur of aortic stenosis is present in fewer than 20% of young infants.[13] An ejection click is often intermittent and may depend on the hemodynamic status of the patient. A prominent gallop rhythm is present in about one-half of the infants with critical aortic stenosis.

In striking contrast to patients with infantile aortic stenosis, older pediatric patients with valvular aortic stenosis are nearly always asymptomatic. Normal growth and development are found in at least 95% of these patients.[46,47] The most common symptom, when any symptom occurs, is easy fatigability. This is a relatively subjective symptom and has been reported in 15% of patients with gradients under 25 mm Hg, whereas over two-thirds of patients with severe aortic stenosis do not have this symptom.[48] Anginal chest pain and syncope are much more specific and worrisome symptoms, but they occur in fewer than 5% of all pediatric patients with aortic valve stenosis. In the Joint Study on the Natural History of Congenital Heart Defects,[48,49] angina did not occur in patients with a gradient less than 25 mm Hg. Angina showed a trend toward increasing incidence (up to 9%) in patients with moderate to severe stenosis. Syncope occurred in less than 5% of patients with gradients under 80 mm Hg and in 9% of patients with gradients over 80 mm Hg. Subjective symptoms alone do not discriminate between mild and severe aortic valve stenosis, but a history of syncope or probable angina demands further evaluation.

The physical findings of aortic valve stenosis in older pediatric patients are characteristic enough that the diagnosis generally can be made on the basis of physical examination. Vital signs, including blood pressure, are normal in all but the most severe cases.[48] Although the shape of the chest is generally normal with no evidence of a precordial bulge, inspection and palpation may provide some clues to the diagnosis. A sustained, visible apical impulse with a presystolic motion indicates left ventricular hypertrophy with prolonged ejection in patients with severe stenosis. The heart is usually normal in size to palpation, but increasing severity leds to an increase in the force of the normal left ventricular impulse. Severe hypertrophy generally is accompanied by a strong and sustained heaving movement of the apex that may be accompanied by a presystolic tap implying an increased force of left atrial contraction in a patient with elevated end-diastolic pressure.[50] A systolic thrill is palpable in up to 85% of patients with even mild aortic stenosis. The thrill is maximal at the upper right or upper left sternal borders radiating cephalad and to the right into the carotid arteries.[48,50] The presence of a precordial (at the lower sternum or apex) thrill by definition indicates a murmur of at least grade IV intensity. Suprasternal notch thrills, however, are common in patients who may have precordial murmurs of only grade II or III intensity.

The murmur of aortic valvular stenosis is a classic "systolic ejection" (systolic crescendo-decrescendo) murmur beginning shortly after the first heart sound or immediately after an ejection click, if one is present. The murmur radiates along the course of the ascending aorta and is usually loudest where the aorta is closest to the precordium (at the right upper sternal border in older children and closer to the left upper sternal border in toddlers). The first heart sound generally is normal but must be distinguished from the ejection click that is present in 60 to 90% of children with valvular aortic stenosis.[10,46,47] The ejection click occurs after the first heart sound and is usually loudest at the left lower sternal border or at the apex. Unlike a pulmonary ejection click, the timing and intensity do not vary with respirations. A soft, low-pitched, and short ejection murmur preceded by a relatively late ejection click is typical of mild aortic stenosis. Increasing degrees of stenosis are accompanied by a louder, higher-pitched, and longer murmur that peaks later in systole. The ejection click occurs closer to the first heart sound with more severe stenosis and may not be audible in patients with critical obstruction.

In mild aortic stenosis, the second heart sound normally is split. With increasing severity of stenosis, left ventricular ejection is prolonged so that the normal widening of the second heart sound with inspiration is diminished. In severe cases, there may be paradoxical splitting of the second heart sound, but more than 80% of patients with severe aortic stenosis still have normal variation of the second heart sound with inspiration.[48] An early diastolic murmur of aortic insufficiency is noted in 15 to 25% of pediatric patients with aortic stenosis.[10,51] This murmur usually is more pronounced in patients with mild or moderate degrees of stenosis. A definite fourth heart sound, which may be accompanied by a presystolic tap, usually indicates significant left ventricular hypertrophy with elevation of left ventricular end-diastolic pressure.

Noninvasive Evaluations

Electrocardiogram

The resting electrocardiogram in infants with critical aortic stenosis is seldom normal, but seldom diagnostic. The frontal plane QRS axis is within normal limits in at least 75% of cases, but both left axis deviation and right axis deviation are seen.[13,14] Right ventricular hypertrophy is the predominant pattern in infants under 1 month of age.[44] Left ventricular hypertrophy is reported in more than three-fourths of older infants.[13,14,43] Inverted T waves and/or ST depression in the left precordial leads (strain pattern) is seen in up to 90% of young infants with critical aortic stenosis.[13,43] Both right and left atrial enlargement are found occasionally as is first degree atrioventricular block. Arrhythmias and more advanced atrioventricular conduction defects are rare.[14] In nearly all series of infantile aortic stenosis, at least one patient wtih severe stenosis and a normal electrocardiogram is reported.[52] In patients under 2 years of age, neither the presence of left ventricular hypertrophy nor the presence of T-wave abnormalities has proven sensitive enough to estimate the degree of severity.[49]

In pediatric patients over 2 years of age, the resting electrocardiogram is only moderately useful in distinguishing the degree of severity of aortic valvular stenosis. The QRS axis is normal in more than 90% of patients.[49] Left ventricular hypertrophy, defined as abnormally high amplitude in V6 (greater than 30 mm or greater than two standard deviations above the mean for age), is more common in patients with more severe stenosis (40% of patients with a gradient less than 25 mm Hg versus 68% of patients with gradients greater than 80 mm Hg).[49] Presence of an S wave greater than 30 mm in lead V1, a very small or absent Q-wave in lead V6, and T-wave inversion in lead AVF all suggest more severe stenosis.[49,53] The most discriminating electrocardiographic parameter may be the T wave in lead V6. The T wave is upright in over 90% of patients with mild or moderate stenosis, but flattened, biphasic, or inverted in 50% of patients with a gradient greater than 80 mm Hg.[49] Serial ECGs showing increasing left ventricular voltage with the development of ST and T wave changes, even

without the development of definite left ventricular hypertrophy may suggest increasing stenosis.[9]

Exercise Test

In patients old enough to cooperate, an exercise electrocardiogram may improve the sensitivity for detecting patients with severe stenosis. Most authors consider the development of ST depression of more than 1 mm persisting longer than 0.08 seconds after the J point to be indicative of possible ischemia.[40] Early reports indicated that a positive treadmill test was highly sensitive and specific for a gradient greater than 50 mm Hg.[54] Later reports, however, found that there is a relatively high false positive rate of up to 40% in patients with a gradient less than 50 mm Hg.[55–57] Some patients with a positive test but low gradient have elevated end diastolic pressure.[58] The test appears to be less useful in postoperative patients.[58]

Maximal exercise capacity is seldom reduced in patients with aortic stenosis.[55,59] An increase in systolic blood pressure greater than 35 mm Hg with exercise is seldom seen in patients with severe stenosis but, unfortunately, many patients with mild stenosis also do not increase their blood pressure by more than 35 mm Hg.[55,57]

Chest Roentgenogram

Patients with infantile aortic stenosis who are symptomatic show generalized cardiomegaly in almost all cases. This enlargement may be severe, particularly in patients under 1 month of age.[13,14,44] Normal heart size has been reported in fewer than 15% of cases.[43,49] Pulmonary vascular markings usually are considered normal but some congestion is reported in 30 to 50%. The ascending aorta is usually not visible in young patients so that dilation of the ascending aorta is seen rarely.[14]

In older patients, roentgenographic findings of cardiac enlargement are present in fewer than 10% of patients with gradients under 65 mm Hg.[9,48] More subtle findings of rounding of the left ventricular apex and posterior displacement of the left ventricular silhouette may be seen in 25% of patients.[46] Although the incidence of cardiomegaly may approach 25% in patients with gradients over 80 mm Hg,[48] there is little correlation between the degree of cardiac enlargement and severity of stenosis.[10] The presence of definite cardiomegaly in an older pediatric patient with aortic valve stenosis suggests either left ventricular failure or the development of significant aortic insufficiency and is associated with a poor immediate prognosis.[60] Dilation of the ascending aorta develops with age. Aortic dilation is seldom seen in patients under 6 years old but is present in 40 to 60% of older patients.[9,10]

Echocardiography

Aortic valvular stenosis was one of the early congenital cardiac lesions identified by m-mode echocardiography. The m-mode features of aortic valve stenosis include multiple diastolic echoes of the aortic valve (instead of the normal single closure line) and apparent asymmetric opening and closure of the valve.[61,62,63] Because the m-mode echocardiogram can be altered markedly by transducer position and angle, two-dimensional echocardiography is superior for evaluating the morphology of the valve.[64] M-mode echocardiography, however, does provide a simple method to measure left ventricular size, wall thickness, and estimate ventricular function. Early studies showed weak correlation of left ventricular shortening fraction, abnormal left ventricular wall motion, or systolic time intervals to severity of aortic valve stenosis.[65–67] Left ventricular peak systolic pressure can be estimated from the m-mode echocardiographic measurements of left ventricular posterior wall thickness in systole (LVPWs) and left ventricular cavity dimension in systole (LVs). Based on the concept that sufficient hypertrophy occurs to maintain normal left ventricular wall stress, the left ventricular systolic pressure (LVPs) is estimated from the formula $LVPs = 225 \times (LVPWs/LVs)$.[68] The aortic valve gradient can be estimated by subtracting the arm blood pressure from LVPs. Unfortunately, this measurement is not reliable in patients with aortic insufficiency. Individual measurements may underestimate or overestimate left ventricular pressure by 20 mm Hg.[68,69]

Two-dimensional echocardiography offers improved evaluation of the morphology of the aortic valve. In the long axis view, the valve usually appears thickened. The symmetry of opening and closing can be evaluated. In diastole, the leaflets often can be seen to prolapse.[70] In systole, the leaflet motion appears restricted and the leaflets often appear to "dome."[64] The aortic valve appears thickened in the short axis view, and the location of the aortic commissures can be evaluated. The typical pattern in diastole is that of a single long commissure that may be either horizontal or vertical.[70] Many bicuspid aortic valves have a raphe that gives the appearance of a tricuspid valve in diastole (Fig. 79–2). Careful analysis of the echocardiogram in slow motion, however, will reveal the typical "fish mouth" appearance of the valve in systole. In some patients, the orifice of the valve can be visualized, but measurement of this orifice area has not proven accurate in determining severity of aortic valve stenosis.[71] Two-dimensional echocardiography is useful in ruling out other sites of left ventricular outflow tract obstruction such as sub- or supravalvular aortic stenosis.[72]

The presence of aortic valvular stenosis results in a high-velocity jet with turbulent blood flow beside and downstream from the jet. These disturbed flow patterns can be identified in the majority of patients by useful examination with pulsed Doppler echocardiography.[73] The presence of disturbed flow on pulsed Doppler is sensitive for identifying the presence of even mild obstruction. Measurement of the velocity of blood in a central jet by continuous wave Doppler is superior to pulsed Doppler for estimating severity of obstruction.

Continuous wave Doppler echocardiography lacks the spatial resolution of pulsed Doppler, but provides a means to measure the high systolic blood flow velocities in the central jet of patients with aortic valvular stenosis. Intuitively, ejecting a fixed amount of flow through a smaller orifice will result in an increase in the veolicty of blood as it is ejected. The instantaneous pressure gradient across a thin obstruction such as a stenotic valve can be accurately estimated from the simplified Bernoulli equation: pressure gradient $= 4 \times$ peak velocity^2 (Fig. 79–3).[74] This formula has been tested extensively in both experimental animals and in humans.[75–79] Unfortunately, this relationship relates instantaneous pressure gradient to instantaneous velocity. In clinical practice, we have traditionally estimated stenosis using the peak-to-peak pressure gradient between the left ventricle and ascending aorta. Since peak pressure in the left ventricle does not occur simultaneously with the peak pressure in the aorta, the highest instanta-

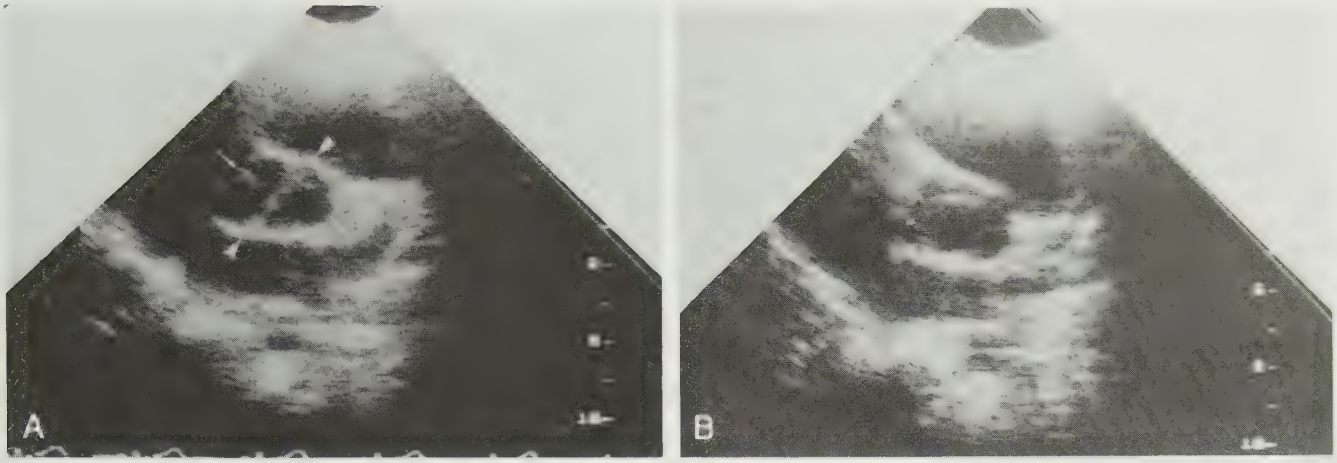

Fig. 79–2. Echocardiogram of mild aortic valvular stenosis. Parasternal short axis views of the aortic valve in diastole (A) and systole (B). The single true commissure (large arrowheads) and raphe (small arrow) are seen in the diastolic frame (A). The prominent raphe almost makes the valve appear tricuspid in diastole, but the fused right and noncoronary cusps are clearly seen as a single line in systole (arrowheads in B).

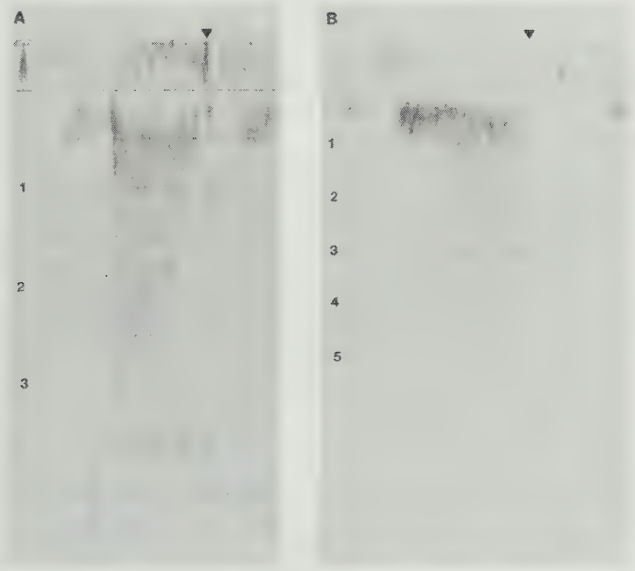

Fig. 79–3. Continuous wave Doppler in aortic valvular stenosis. Tracings from the apical window in a patient with mild stenosis (A) and severe stenosis (B). Peak velocity in (A) is 2.7 m/sec, which yields an estimated peak instantaneous gradient of $4 \times (2.7)^2 = 29$ mm Hg. The peak velocity occurs early in systole and velocity is very low immediately prior to valve closure (arrowhead). Peak velocity in (B) is 4.8 m/sec, which yields an estimated peak instantaneous gradient of $4 \times (4.8)^2 = 92$ mm Hg. The highest velocities occur later in systole than in a patient with mild stenosis, and the velocities remain high (indicating a continued gradient) very late systole.

neous gradients measured by Doppler echocardiography usually are higher than the cardiac catheterization peak-to-peak gradients (Fig. 79–4). Doppler-derived pressure gradients do not overestimate true pressure gradients, but if the maximal Doppler peak intantaneous pressure gradient is equated incorrectly with the peak-to-peak systolic gradient, overestimation is the rule.[80]

Determination of the mean pressure gradient from the Doppler signal is somewhat more tedious but correlates very well with the mean pressure gradient at catheterization.[79,81–83] Mean pressure gradients are not used commonly in pediatric cardiology but can be used to calculate valve area. This technique has proven relatively accurate in adult patients.[81,82]

Some variation between measurements performed during catheterization and nonsimultaneous echocardiographic measurements must be expected because of differences in cardiac ouput related to sedation or sympathetic tone, as well as inaccuracies introduced by the use of fluid-filled catheters.[78,84,85] Doppler tracings should be obtained from suprasternal notch, right parasternal, and apical windows in aortic stenosis patients with the highest velocities obtained for gradient calculations. Because of the importance of the Doppler gradient estimate in following patients with aortic stenosis, we do not hesitate to use sedation in uncooperative patients in order to obtain high-quality tracings.

In patients with infantile aortic stenosis, echocardiography is sufficiently sensitive and specific to eliminate the need for diagnostic cardiac catheterization in many critically ill patients.[86–88] Two-dimensional echocardiography demonstrates a thickened and abnormal appearing aortic valve with markedly reduced mobility. In symptomatic patients, the thickened leaflets are always visible in both systole and diastole (Fig. 79–5). Extremely thickened valves will show very little motion through the cardiac cycle. M-mode and two-dimensional echocardiography may be used to evaluate left ventricular size, which may be an important prognostic factor.[22] The left ventricle typically appears hypertrophic. An abnormally increased echodensity of the papillary muscles of the mitral valve is seen.[89] Right ventricular enlargement and poststenotic dilation of the ascending aorta are usual in patients with symptomatic infantile aortic valvular stenosis. A complete, sys-

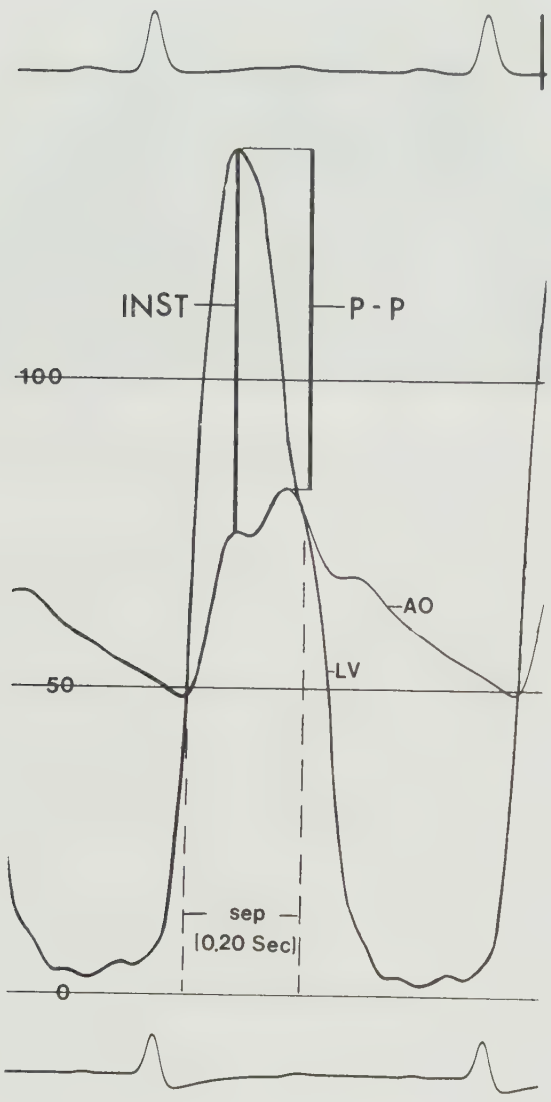

Fig. 79–4. Valve gradient and valve area from catheterization data. Simultaneous left ventricular (LV) and aortic (Ao) pressure curves in moderate aortic stenosis are shown. The peak-to-peak (P-P) pressure is the difference between the maximal LV pressure and maximal aortic pressure (54 mm Hg in this patient). Maximal instantaneous gradient (INST) is the maximal difference between aortic and let ventricular pressure at any instant in systole (62 mm Hg in this patient) and is usually slightly higher than P-P. To calculate indexed aortic valve area (AVA), one must know the amount of time during which blood is flowing through the stenotic valve (SEP) and the amount of blood flowing through the orifice—the cardiac index (CI). From the tracing above, the time of one systole (sep) is 0.2 sec and if the heart rate (HR) is 100/min, then SEP = sep × HR = 20 sec/min. The Bache formula[100] for calculation of the aortic valve area is: $AVA = Q/37.8\sqrt{(P+P) + 10}$ where Q = CI/SEP in this example, CI = 4000 ml/min/M². Therefore, $Q = 4000/(100 \times 0.2) = 200$ and $AVA = 200/(37.8\sqrt{59+10}) = 0.66$ cm²/M².

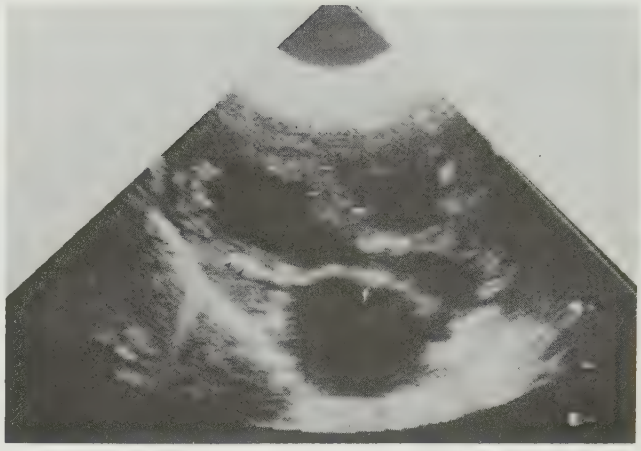

Fig. 79–5. Echocardiogram of infantile aortic stenosis. Systolic frame of parasternal long axis view of the left ventricle and proximal ascending aorta. The mitral valve is closed, and there is abnormal echodensity of the papillary muscle (black arrowheads). Persistent echoes of the aortic valve are still visible in the aortic root (white arrow). There is poststenotic dilation of the ascending aorta.

temic echocardiographic examination of the heart and great vessels is imperative to rule out associated lesions in patients who may be sent to surgery without cardiac catheterization. Pulsed Doppler echocardiography confirms the presence of disturbed flow in the ascending aorta. In patients with very poor cardiac output, the systolic flow may not suggest a high gradient (especially if much of the systemic flow is provided through a patent ductus arteriosus), but a small jet of disturbed flow should be detectable. Doppler also is useful for evaluating the presence and severity of aortic or mitral insufficiency and for identifying the presence of a patent ductus arteriosus.

Cardiac Catheterization

Although many patients with infantile aortic stenosis can be referred for surgery after complete echocardiography, cardiac catheterization is still indicated if there is any doubt about the diagnosis or if associated defects such as coarctation of the aorta cannot be completely evaluated with the noninvasive evaluations. Combined left and right heart catheterization will help evaluate the possibility of associated lesions. For diagnostic catheterization, we prefer to enter the left ventricle prograde via the foramen ovale or utilizing the Mullins long transseptal sheath technique.[90] This approach allows certain access to the left ventricle without the need to manipulate a catheter across the sometimes tiny orifice of the stenotic aortic valve. We prefer to measure the aortic valve gradient by simultaneously recording the left ventricular pressure and the ascending aortic pressure (through a small umbilical or femoral arterial catheter advanced retrograde to the ascending aorta). Femoral arterial pressure or brachial artery pressure can be substituted for the ascending aortic pressure in infants since the decision for surgery is usually not based solely on gradient measurements in this age group.

The aortic valve is best demonstrated angiographically by performing both left ventricular and aortic root angiograms.[91] We prefer the use of nonionic contrast media, particularly in patients with severe stenosis, because there is less vasodilation and less

depression in contractility. Left ventriculography is best performed with the long axial (60 degrees left anterior oblique plus 30 degrees cranial-caudal angulation) and elongated right anterior oblique (30 degrees right anterior oblique plus 30 degrees cranial-caudal angulation) projections.[92,93] These views minimize the appearance of structures overlying the left ventricular outflow tract and allow the best visualization of the subaortic and supravalvular areas. The stenotic aortic valve typically appears thickened and domes in systole.[68] There is a central jet of contrast that corresponds to the orifice of the stenotic valve (Fig. 79–6). In patients with a unicuspid valve, the jet of contrast is more likely to be directed posteriorly (in contact with the posterior wall of the aorta). In diastole, one can see a deep sinus of Valsalva anteriorly with a shallow posterior sinus in the case with a unicuspid valve.[94] The presence of extensive myocardial sinusoids suggests the presence of endocardial fibroelastosis.[21] Left ventricular volume and ejection fraction can be compared to normal values for age.[95]

Beyond the neonatal age group, cardiac catheterization for aortic valvular stenosis is performed primarily in patients with borderline criteria for surgery. Catheterization is not necessarily indicated in patients who are obvious surgical candidates based on noninvasive evaluations, and certainly catheterization is not needed in patients who have unequivocal evidence of only mild stenosis.

Hemodynamic measurements should be obtained prior to angiograms. The left ventricle can be entered using either the retrograde or transseptal approaches. If a long transseptal sheath is used to gain access to the left atrium, the left ventricle can then be entered using a straight catheter and preformed guiding wire, balloon tipped catheter, or modified pigtail catheter.[90,96,97]

Unless the transseptal catheter can be manipulated progradely across the aortic valve, measurement of the gradient requires placement of a retrograde arterial catheter in the ascending aorta. The gradient across the aortic valve should be measured by either simultaneous left ventricular and ascending aortic pressure tracings or by pullback tracing from the left ventricle to the ascending aorta. Femoral arterial pressure should not be substituted for ascending aortic pressure. In older patients with borderline gradients, pulse amplification results in higher systolic pressure in the femoral artery than in the ascending aorta and thus an underestimation of the severity of the gradient to an unpredictable degree.[98,99] In general, increasingly severe stenosis results in a more rounded or peaked appearance to the left ventricular pressure curve with an earlier and lower anacrotic notch on the aortic pressure curve. Cardiac output should be measured using either the Fick technique or an indicator dilution method. Aortic valve area can be calculated from the Gorlin formula or the simplified formula proposed by Bache (see Fig. 79–4).[30,100] The advantage of the Bache method is that planimetry is not required. The aortic valve must be indexed to body surface area in pediatric patients. The normal aortic valve area approximates 2 cm^2/M^2 body surface area; valve areas greater than 0.7 cm^2/M^2 signify mild obstruction, and valve area less than 0.5 cm^2/M^2 indicates severe obstruction. After hemodynamic measurements, left ventricular and aortic root angiograms routinely are performed to evaluate left ventricular function, ventricular hypertrophy, morphology of the aortic valve, degree of aortic insufficiency, and degree of mitral insufficiency.

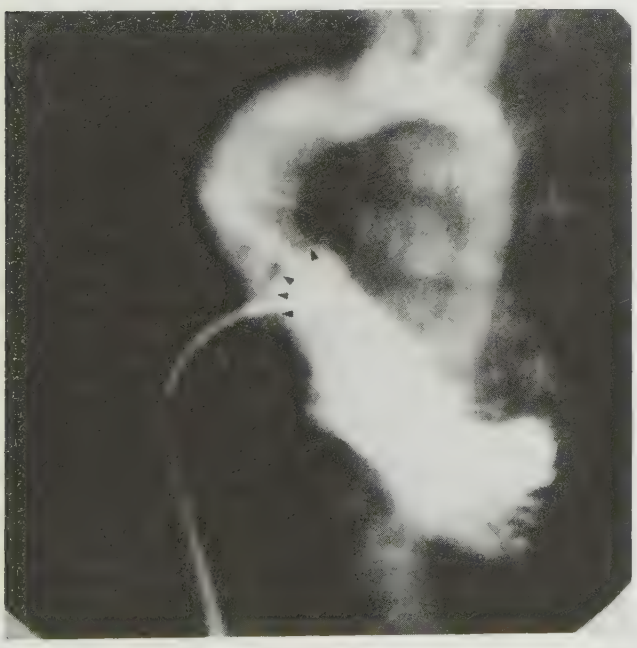

Fig. 79–6. Left ventriculogram in aortic valvular stenosis. Long axial oblique view of left ventricle in systole. The thickened aortic valve is domed (arrowheads), and a small jet of contrast is seen being ejected through the eccentric valve opening.

Treatment and Followup

Infants with aortic stenosis severe enough to cause definite symptoms of congestive heart failure are considered to have critical aortic stenosis of infancy. Such patients can deteriorate rapidly and may present a medical emergency. Those with severe heart failure and poor perfusion should be treated aggressively with inotropic support and mechanical ventilation, if necessary. In young infants, prostaglandin E_1 infusion to open the ductus may have beneficial effects,[101,102] but the potential to reduce systemic blood pressure if the ductus does not reopen should be kept in mind.[103] Following stabilization, noninvasive evaluation is obtained quickly. Echocardiographic evaluation is sufficient in many cases. If significant questions remain about the diagnosis or associated lesions, the patient is referred for diagnostic cardiac catheterization. Pressure gradient is not a reliable criterion for severity in patients with an open ductus (and right to left shunting) or low cardiac output. The presence of an angiographically abnormal aortic valve and significant symptoms is sufficient to make the diagnosis of critical aortic stenosis. Prolonged medical treatment is contraindicated because of the potential for sudden deterioration and nearly uniform failure to eliminate signs of congestive heart failure.[13,14,43] Sustained symptomatic improvement can only be expected following procedures to open the aortic valve. Surgical aortic valvotomy remains the standard approach.

Patients surviving surgery for infantile aortic stenosis often show marked clinical improvement, but there is a very high surgical mortality. Early series reported operative mortalities over 50% in symptomatic infants.[13,20] More recent reports suggest that the operative mortality has been reduced to the 25 to 50% range,[43,45,104,105] but long-term survival remains disturbingly low.[103] The high mortality may be related to associated abnormalities including mitral insufficiency with infarction of the papillary muscles,[19] small left ventricular size,[21,43] small aortic or mitral annulus,[103] or the presence of endocardial fibroelastosis.[21] Results appear to be similar whether the valvotomy is performed with inflow occlusion, total cardiopulmonary bypass, or deep hypothermia and circulatory ar-

rest. Most surgeons now prefer to perform a relatively limited valvotomy in these critically ill infants designed to produce a moderate improvement in left ventricular valve gradient without inducing severe aortic insufficiency.[104,106] This limited valvotomy may be lifesaving but should be considered palliative in some respects because of a high incidence of residual or recurrent stenosis and significant aortic insufficiency.[43,45,104]

The treatment of aortic valvular stenosis beyond the infant age group is primarily expectant. There is no question that progression in severity of aortic stenosis with age is the rule rather than the exception. Serial studies have demonstrated that the aortic valve gradient should be expected to increase in over three-fourths of patients with even mild stenosis over a 5- to 10-year period.[9,46,47] More than 50% of patients with moderate aortic stenosis at 6 to 8 years will be surgical candidates by 13 to 15 years of age. It appears that the aortic valve orifice is relatively fixed in pediatric patients and does not increase with growth.[107,108]

The most frightening complication of aortic stenosis in pediatric patients is sudden death. Among unoperated patients, aortic stenosis has been one of the most common causes of sudden death due to heart disease in pediatric patients.[109,110] Virtually all cases of sudden death attributed to aortic valvular stenosis have been associated with evidence of at least moderately severe obstruction. Many patients have had previous symptoms of angina or syncope. The majority have had left ventricular hypertrophy with strain on the ECG.[109–111] About half of the sudden deaths in aortic valvular stenosis have occurred during or immediately after exercise.[109] Prior to the widespread availability of echocardiography and treadmill exercise testing, noninvasive evaluation of the severity of aortic stenosis in pediatric patients was felt to be inaccurate enough that routine serial cardiac catheterization was recommended for all patients.[46,47]

In our practice, we do not routinely catheterize/recatheterize patients who have clear echocardiographic evidence of less than moderately severe stenosis with normal resting and exercise ECG. Exact recommendations for the classification of severity of aortic valve stenosis vary from center to center.[9,47,48,112] In our practice, we consider patients with a transvalvular gradient of less than 25 mm Hg to have trivial aortic stenosis. We do not recommend any restrictions in physical activities in these patients and generally see them for noninvasive evaluation every 1 to 2 years. We typically perform at least one echocardiographic and Doppler examination to verify the trivial nature of the lesion and repeat the echocardiographic evaluation if there are any changes in clinical or ECG indicators of severity.

Patients who have a gradient of 25 to 50 mm Hg by invasive or noninvasive studies are considered to have mild aortic stenosis. Restrictions in recreational activity are not needed in this group of patients if the treadmill test is normal.[113,114] Because of the likelihood of progression, we generally counsel parents not to encourage these children to become active in competitive athletics that require a great deal of physical conditioning. These patients are followed noninvasively every 1 to 2 years. Echocardiography is performed every one to two years and exercise stress testing is done at least once and repeated with any change in clinical or echocardiographic indicators of severity. Patients who have symptoms or definite abnormalities on the resting or exercise ECG are considered for hemodynamic evaluation. In mild aortic stenosis, the aortic valve area at catheterization should be greater than 0.7 cm^2/m^2.

Patients with a peak to peak gradient of 50 to 75 mm Hg are considered to have moderate aortic stenosis. Patients with moderate aortic stenosis are restricted from activities involving more than light exercise such as recreational swimming, bicycling, or golf.[113] Patients in this category with a normal treadmill exercise test and no symptoms are followed with yearly echocardiographic and treadmill exercise tests. Abnormalities developing in these noninvasive evaluations would be an indication for surgery without catheterization if the gradient is felt to be on the high side of this range. It must be remembered that the instantaneous gradient by Doppler echocardiography usually overestimates the peak to peak gradient (particularly if the patients are not sedated). Therefore, potential surgical candidates with an estimated gradient closer to 50 mm Hg are usually referred for cardiac catheterization. Surgery is indicated for a resting cardiac catheterization gradient over 50 mm Hg or a valve area less than 0.7 cm^2/m^2 in patients who have T-wave changes on resting or exercise ECG or who have symptoms possibly attributable to aortic stenosis. We would also consider intervention in a patient with moderate stenosis who has a very strong desire to compete in more rigorous athletics than we would allow with a gradient of 50 to 75 mm Hg.

Patients with a peak to peak gradient over 75 mm Hg have severe aortic stenosis and are considered to be surgical candidates even without symptoms and without T-wave changes. Those with clear echocardiographic evidence of severe stenosis may be referred for surgical intervention without prior cardiac catheterization. However, cardiac catheterization may be required in some of these patients who are thought to have a very high gradient predicted by echocardiography and no other indications of severity. All patients with aortic stenosis should observe SBE prophylaxis regardless of the severity of the lesion.

Surgery

The standard surgical procedure for pediatric patients (outside the infantile group) meeting criteria for intervention is an open surgical valvotomy. Valvotomy is technically possible because of the relatively pliable valve leaflets and general absence of calcification in patients under 18 years of age.[10] Aortic commissurotomy generally is performed using cardiopulmonary bypass. The commissures are incised to free the fused valve leaflets but the incision is not carried completely to the annulus.[106] Care must be taken not to incise a false commissure since this appears to produce increased aortic insufficiency.[10] Intraoperative measurement of the gradient after weaning from cardiopulmonary bypass has shown a good correlation with early postoperative cardiac catheterization.[115] Operative mortality for surgical aortic valvotomy outside the infant age group is now approximately 2%.[116–118]

Nearly all patients show a reduction in valve gradient and improvement in symptoms after surgical aortic valvotomy. However, longterm followup studies have shown that significant late problems develop in a high percentage of patients. Survival at 10 to 20 years postoperatively has been estimated at 88 and 77%, respectively.[118,119] At 10 years after surgery, 50% of patients will suffer from residual aortic stenosis with a gradient over 50 mm Hg, moderate or severe aortic insufficiency, reoperation, bacterial endocarditis, or late death.[116,118] The risk of sudden death is not completely eliminated by surgical valvotomy. However, the ma-

jority of patients who die suddenly late postoperatively have evidence of moderate or severe aortic insufficiency or residual aortic stenosis.[116,118,120] Nearly all pediatric patients with aortic valve stenosis have normal ventricular function at the time of surgery unless they have significant aortic insufficiency; poor ventricular function is generally expected to improve following relief of stenosis.[121]

Aortic insufficiency is seen in approximately two-thirds of patients following aortic valvotomy in most large series. About half of this group will have mild aortic regurgitation and in the other half the aortic regurgitation will be moderate or severe.[116,122] Patients with moderate or even severe aortic insufficiency may be asymptomatic for many years, but eventually will develop increasing left ventricular size and signs of left ventricular dysfunction. There is no indication for "prophylactic" aortic valve replacement in pediatric patients with even severe aortic insufficiency. Surgical intervention, however, must be considered in patients who develop significant left ventricular dysfunction (most easily assessed by an echocardiographic shortening fraction less than 25%), progressive left ventricular dilation (especially if the end systolic volume is greater than 60 mL/m^2), or definite symptoms of reduced exercise tolerance (best assessed by serial treadmill exercise tests).

Patients who develop recurrent stenosis may be candidates for repeat valvotomy if the initial procedure was performed in infancy. Repeat valvotomy does not appear to be beneficial in most patients who had their first operation at a later age.[123] Bacterial endocarditis remains a significant contributor to late mortality and morbidity.[108,118] Ventricular arrhythmias, may indicate a significant risk, both preoperatively and postoperatively.[124] An uncommon late complication is dissecting aneurysm of the ascending aorta caused by injury to the vessel wall from the high velocity jet of blood caused by the stenosis.[125]

Re-operation for progressive aortic insufficiency or recurrent stenosis usually entails aortic valve replacement. Although bioprosthetic valves initially seemed ideal for pediatric patients because of the reduction in need for anticoagulation, a very high incidence of valve failure was found in this age group. In some series, the incidence of tissue valve failure was as high as 8 to 20% per year. Most centers now prefer mechanical valves in nearly all pediatric patients with aortic valve stenosis.[126,127] Systemic anticoagulation with warfarin is generally recommended following placement of a mechanical prosthetic aortic valve in older pediatric patients.[128] Younger pediatric patients may be more resistant to thromboembolic events and antiplatelet agents may be sufficient, especially in children under 5 years of age who are at more risk for complications of systemic anticoagulation because of their activities.[128,129] This issue, however, remains controversial and some centers only employ antiplatelet agents in all ages.[130] Re-operation for aortic valve replacement carries a significantly higher operative mortality than the original procedure (5 to 12%), but medium-term survival is good at 86 to 94%.[118,126,129]

Patients with a small annulus either due to young age or a truly hypoplastic left ventricular outflow tract represent a special problem. Placement of a conduit from the left ventricular apex to the abdominal or thoracic aorta results in good initial relief of gradient.[131–133] However, the need for late re-operation due to conduit valve failure or progression of insufficiency of the native aortic valve has limited the utility of this procedure.[132,133] Enlargement of the aortic annulus by incision of the ventricular septum to allow placement of at least a 19 mm valve (modified Konno procedure) has proven feasible, and early results appear excellent.[134–137]

Balloon Aortic Valvotomy

Interventional cardiac catheterization procedures have developed rapidly in the last 10 years and have gained wide acceptance for some lesions. Following development of techniques for balloon valvuloplasty of pulmonary stenosis and demonstration of its safety and effectiveness, balloon valvuloplasty of aortic valvular stenosis was reported in 1983.[138,139] Since then, a number of series have been published on the use of this technique in pediatric patients.[28,140–142] In general, early results from this procedure have shown results similar to those of surgical valvotomy with approximately a 50% reduction in gradient in most patients and resulting gradients of less than 50 mm Hg in approximately 90% of patients. Development of new or slightly increased aortic regurgitation is common (as it is with surgical aortic valvotomy). Development of early postprocedure aortic insufficiency of moderate or severe degree appears to occur in approximately 10% of patients using current techniques.[142,143] Long-term results of this procedure are not yet available. The techniques for performing this procedure are still developing.[142,144,145] There are reports of mortality associated with this procedure,[144,146] but early results from the Valvuloplasty and Angioplasty of Congenital Anomalies Registry suggest that mortality is less than or equal to that of surgical valvotomy (unpublished data). Minor complications from the procedure have occurred in up to 27% of patients.[143] The most frequent complication has been transient pulse loss in the leg where the arterial balloon catheter is introduced. It is currently unclear whether the use of two smaller balloons will prove superior to the use of a single large balloon in avoiding this or other complications. Because of the relatively small number of procedures done to date and the lack of long-term followup, this procedure is still considered experimental in most centers, but holds a promise as an alternative to surgical valvotomy to palliate young patients and hopefully delay the need for aortic valve replacement.

SUPRAVALVULAR AORTIC STENOSIS

Supravalvular aortic stenosis is the least common of the three types of fixed aortic stenosis. The pathologic anatomy was first described by Cheevers in 1842.[147] In 1961, Williams reported a series of four patients who had supravalvular aortic stenosis, mental retardation, and unusual facial features.[148] In larger series, it appears that 28 to 50% of patients with supravalvular aortic stenosis have the Williams syndrome, approximately 20% have a familial form of supravalvular aortic stenosis without the other characteristics of Williams syndrome, and approximately 50% have a sporadic form of the defect.[147,149,150] Excessive vitamin D in the pregnant rabbit results in offspring that have craniofacial abnormalities and supravalvular aortic stenosis.[151] However, in humans, it is unusual to find either a history of excessive vitamin D intake during pregnancy or infantile hypercalcemia in affected patients.[152,153] In most series, males and females are approximately equally affected.

Anatomy and Embryology

Three morphologic forms of supravalvular aortic stenosis are usually reported. Fifty to 75% of patients have an "hourglass"

deformity with a constricting ridge at the superior margin of the sinuses of Valsalva.[147,149] Histologically, there is marked thickening of the media in the region of this ridge with disorientation of the medial cells as well as thickening and increased collagen content in the intima.[147,154] Approximately 25% of patients have a more diffuse type of narrowing extending for a variable distance along the ascending aorta.[149] Some series report a rare patient with a discrete membrane above the valve. This may actually be a more localized variety of the hourglass deformity.[147,155]

Although the immediate supravalvular area is the most significant area of stenosis, it is also very common for the origins of the major branches of the aortic arch to be involved.[154] Most patients also have at least minor abnormalities of the aortic valve, which is often thickened and has abnormal attachments to the supravalvular ring.[149,154] These abnormal attachments may be responsible for coronary artery stenosis.[154] Most patients with supravalvular aortic stenosis—particularly if they have Williams syndrome—also have evidence of right ventricular outflow tract obstruction that can occur at the valvular, supravalvular, or peripheral pulmonary arterial levels. The exact incidence of right ventricular outflow tract obstruction is difficult to ascertain since there is a peculiar tendency for the obstruction to improve considerably with age.[152,153]

Physiology

The major pathologic derangement in supravalvular aortic stenosis is very similar to that in aortic valvular stenosis. There is increased systolic work resulting in left ventricular hypertrophy. In most patients with supravalvular aortic stenosis, the coronary arteries are enlarged and experimental studies have shown that total mean coronary blood flow increases after supravalvular aortic constriction. However, coronary flow in diastole appears to be the major determinant of the development of ischemic changes, and diastolic flow to the coronary arteries in fact decreases significantly.[156] During exercise, the endocardial/epicardial coronary flow ratio decreases significantly in dogs with a supravalvular aortic band compared to animals with similar degrees of systolic pressure caused by renal hypertension.[157]

The systolic jet created by supravalvular aortic stenosis seems to persist along a greater distance than the jet caused by the discrete obstruction of aortic valvular stenosis. This high-velocity jet has a tendency to "hug" the wall of the aorta and transfer much of the kinetic energy into the brachio-cephalic vessels. This phenomenon, called the Coanda effect, has been demonstrated to be the explanation for the marked discrepancy in blood pressures with the right arm pressure higher than the left arm in most patients with supravalvular aortic stenosis.[158,159]

Clinical Features

Clinical features of supravalvular aortic stenosis are very similar to those of aortic valve stenosis. The majority of patients come to evaluation because of the presence of a systolic murmur. The murmur closely resembles that of aortic valvular stenosis. However, the finding of an aortic ejection click is unusual. The aortic valve closure sound may be increased.[160] Suprasternal notch thrills are very common. Because there is a high prevalence of ostial stenosis of the aortic arch vessels, discrepancies between carotid pulsations should be sought carefully. Blood pressures in both arms and in the legs should be obtained. As many as 86% of patients with supravalvular aortic stenosis will have a discrepancy in blood pressure between the arms of at least 5 to 10 mm Hg (right arm greater than left arm 80% of the time).[159]

Because individual series tend to be small, it is difficult to ascertain the incidence of symptoms. However, in most surgical series, a high portion of patients have significant disability. Dyspnea on exertion and angina are noted commonly. About two-thirds of patients have additional cardiovascular abnormalities, including pulmonary stenosis, coarctation, patent ductus arteriosus, and mitral insufficiency. When carefully sought, associated valvular and subvalvular aortic stenosis will be present in up to one-third of patients.[150] Williams syndrome is discussed in greater detail in Chapter 144. Patients with Williams syndrome have characteristic "elfin" facies, stellate iris pattern and husky voice.[161] Most of these patients are small in infancy (< 5th percentile until 3 years of age) but eventually attain normal stature.[152] Moderate to severe mental retardation is a consistent, but not universal, finding.[152] The children are often verbal and outgoing with a "cocktail personality." Most of these patients are relatively thin and have been confused with variants of Marfan's syndrome.[160]

Noninvasive Evaluations

The electrocardiogram is usually abnormal in patients with supravalvular aortic stenosis. In young patients, right ventricular hypertrophy is found commonly. In most older patients, left ventricular hypertrophy is observed, and the strain pattern is common in surgical series.[150,154] The chest x-ray is most often normal but may show mild to moderate cardiomegaly with evidence of left ventricular hypertrophy.[149,160] Dilation of the ascending aorta is distinctly absent.

Echocardiography is a valuable tool in the evaluation of patients with supravalvular aortic stenosis. The m-mode echocardiogram is useful for determining the degree of left ventricular hypertrophy. Careful "sweeps" from the left ventricle to the ascending aorta can demonstrate a narrowed area above the aortic valve with a more normal aortic dimension above the area of stenosis. However, this is a technically difficult procedure in many patients and the m-mode echocardiogram tends to underestimate the severity of the supravalvular narrowing.[162–164] More recent studies have demonstrated the utility of two-dimensional echocardiography, and this has proved to be an excellent way to demonstrate the supravalvular narrowing in our experience (Fig. 79–7).[165] Careful pulsed Doppler examination will reveal the development of turbulence and high velocity distal to the aortic valve and in the region of the supravalvular narrowing. Doppler estimates of the pressure gradient across a long supravalvular narrowing may not be as accurate as those across a more discrete narrowing such as aortic valvular stenosis.[166] Magnetic resonance imaging can also be used to demonstrate the ascending aorta and the supravalvular aortic narrowing.[167]

Cardiac Catheterization and Angiography

Because of the high incidence of associated abnormalities, it is essential that both left and right heart catheterization be performed in patients with suspected supravalvular aortic stenosis. The left ventricle can be entered using either the transseptal approach or retrograde approach. It is usually not difficult to cross the supravalvular obstruction from the retrograde approach since there is usually a funnel-shaped opening above the obstruction as well as

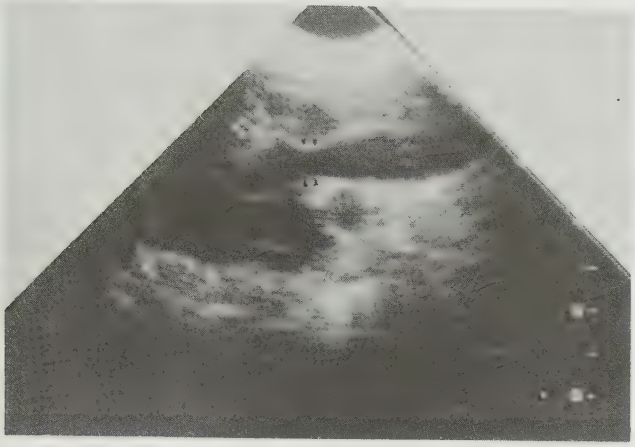

Fig. 79–7. Echocardiographic appearance of supravalvular aortic stenosis. Long axis view of ascending aorta obtained from a high parasternal window. The hourglass shape of the aorta and supravalvular narrowing (arrowheads) are visible. The aortic valve and left ventricle may be difficult to see at the same time that this portion of the aorta is well visualized.

below the obstruction. Careful pullback tracings utilizing a catheter with an endhole or closely spaced sideholes allow detection of additional gradients across the subvalvular or valvular areas. We recommend a right ventricular angiogram if there is elevation of right ventricular pressures to evaluate for peripheral pulmonary branch stenosis.[153]

A bi-plane left ventriculogram in either the AP and lateral or long axial oblique and lateral views will show the supravalvular narrowing and the ascending aorta (Fig. 79–8). Because of the high incidence of stenosis of the arch vessels, it is advisable to include these in the angiographic field.[168] An aortic root injection is also recommended to demonstrate possible coronary arterial stenosis and to detect aortic insufficiency.[149,169] Catheterization in patients with severe supravalvular aortic stenosis is not without risk, and sudden death has been described with angiography in these patients.[154]

Natural History

The natural history of supravalvular aortic stenosis without surgery is difficult to ascertain since reliable differentiation from aortic valvular stenosis was unavailable until after surgical intervention was well established. As mentioned previously, there is a high incidence of symptoms in older patients with supravalvular aortic stenosis. The few series with patients who have undergone serial cardiac catheterizations have suggested that the right ventricular obstructive lesions, which may predominate in infancy, often improve with age.[152,153] However, the supravalvular aortic stenosis tends to remain unchanged or occasionally becomes dramatically worse over a fairly short period of time.[149,150,153] Sudden death has been reported in a small number of patients.[149,154]

Treatment

Indications for surgical intervention in supravalvular aortic stenosis are similar to those in aortic valvular stenosis. Good results have been demonstrated in patients with the discrete type of supravalvular aortic stenosis. The standard approach is a lateral aortotomy into the noncoronary cusp followed by resection of the supravalvular obstruction and insertion of a dacron patch over the aortotomy.[149,150] Operative mortality is approximately 5%, and adequate reducton in gradient occurs in most patients. Small residual gradients between the aorta and left ventricle are common but may be due to coexistent valvular or subvalvular stenosis.[149] Aortic

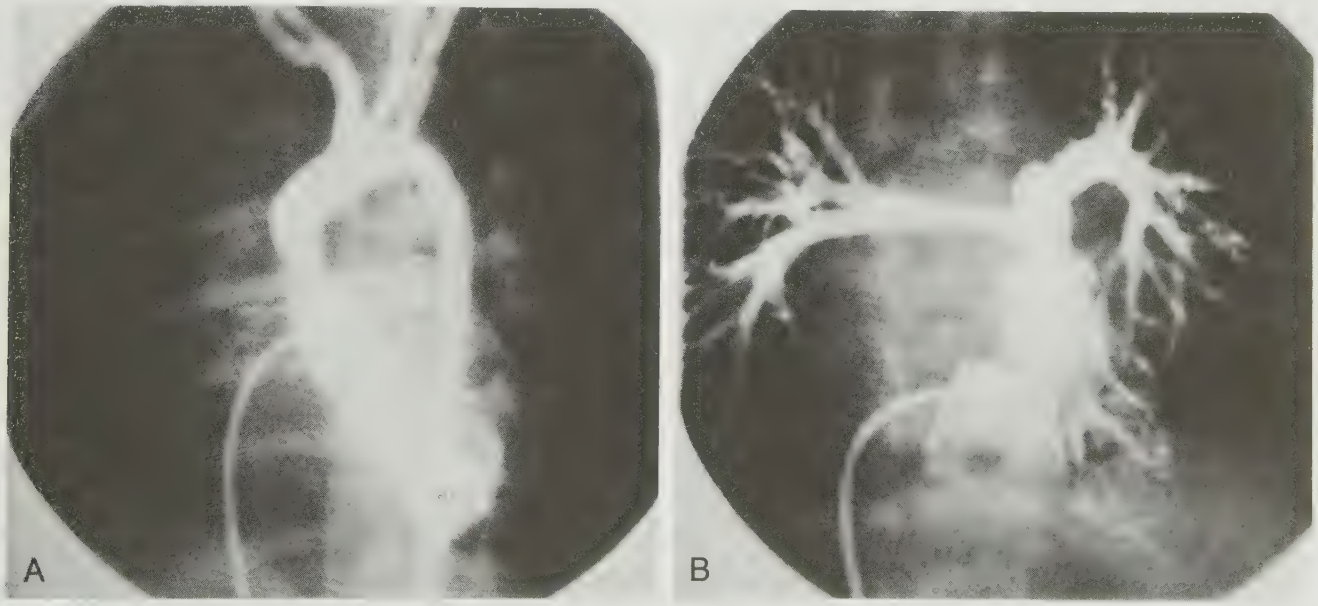

Fig. 79–8. Angiographic appearance of supravalvular aortic stenosis. (A) Long axial view of the left ventricle and aortic arch in a patient with moderate supravalvular aortic stenosis. There is a narrow segment of ascending aorta immediately above the aortic valve. The left coronary artery is dilated, and the origin of the left common carotid artery is narrowed mildly. (B) Cranially angulated view of right ventriculogram showing supravalvular narrowing of the main pulmonary artery and diffuse narrowing of the right pulmonary artery. These vessels appeared much more normal, and right ventricular pressure decreased significantly at repeat catheterization 1 year later.

valve insufficiency is present in approximately 25% of patients postoperatively. In most patients, the aortic valve continues to appear abnormal angiographically because of attachment of the aortic valve cusps to residual supravalvular tissue.[149]

The hypoplastic form of supravalvular aortic stenosis is considerably more difficult to treat surgically.[170] Particularly in earlier series, operative mortality was high and relief of gradient was less than in patients with the discrete form of supravalvular aortic stenosis. It is not clear whether more extensive aortoplasty will be completely successful in reducing the gradient in these patients.[171] Alternative procedures, including the apical left ventricle to descending aorta valved conduit, have had some success.[106,150] The majority of patients who have undergone surgery are asymptomatic. But the long-term fate of the native aortic valve, coronary vasculature, and cerebral vasculature are not known. Re-stenosis at the site of original repair does not appear to be a common problem, but the long-term fate of the distorted aortic valve is uncertain.[149] Patients who have left ventricle to aorta conduits will be at significant risk for late complications.[132,133]

FIBROMUSCULAR SUBVALVULAR AORTIC STENOSIS

Fibromuscular subvalvular aortic stenosis is the second most common form of fixed aortic stenosis, occurring in 8 to 20% of pediatric patients in most series.[171–173] As with aortic valvular stenosis, males are affected two to three times as often as females.[172,173] Unlike aortic valvular stenosis, severe subvalvular stenosis is almost never seen in newborns and only rarely in infants.[175,176] Associated cardiac malformations are more common than in patients with valvular aortic stenosis, occurring in 50 to 65% of patients.[172,177,178] The most commonly associated lesions are ventricular septal defect, coarctation of the aorta, patent ductus arteriosus, left superior vena cava, and aortic valvular stenosis.

Anatomy and Embryology

Subvalvular aortic stenosis can be caused by a thin discrete membrane, a thicker diaphragm with a muscular base (termed a collar or ridge) or a diffuse tunnel-like narrowing of the left ventricular outflow tract.[6,172,77] Seventy-five to 85% of patients have the membranous-type of obstruction. In these patients, there is a crescent-shaped, fibrous curtain attached to the ventricular septum or completely encircling the left ventricular outflow tract, located anywhere from immediately below the aortic valve to 1 cm or more into the body of the ventricle. In most series, about 10% of patients are considered to have a lesion similar to the membrane but somewhat thicker and usually associated with some protrusion of a thicker, muscular base. The distinction between this collar or ridge is often not clear-cut and not made by all authors.[172,174,177] The tunnel-type of subaortic stenosis is seen in 10 to 15% of these patients.[172,179]

There is clinical and experimental evidence that fixed subvalvular subaortic stenosis is an acquired lesion with an underlying ill-defined congenital disorder.[178] Careful study of familial subaortic stenosis in Newfoundland dogs demonstrated that subaortic stenosis develops postnatally but has a specific genetic pattern of inheritance.[180] The substrate for this postnatal development is not well understood. Rosenquist noted an increased mitral–aortic separation due to a muscular wedge in humans.[181,182] It is possible that abnormal flow patterns associated with this abnormality could lead to abnormal proliferation of tissue. Persistent embryonal endocardial cushion tissue that retrains its proliferative capacity has also been suspected.[180,183,184] Familial occurrence of subaortic stenosis in humans has been reported.[185]

Physiology

The physiology of isolated subvalvular aortic stenosis appears to be identical to that of aortic valvular stenosis. Left ventricular hypertrophy develops in response to high systolic pressures. In most patients, the degree of hypertrophy appears to be appropriate, but may be asymmetric and associated with apparent increased contractility in some patients.[6,179,186] The aortic valve frequently is thickened in patients with subvalvular aortic stenosis but is usually tricuspid. This valvular abnormality also seems to be acquired and has been ascribed to a jet lesion from the subvalvular stenosis. Trauma to the valve may be the etiology of the high incidence of aortic insufficiency seen in these patients.[6,173]

Clinical Features

The clinical findings in young patients with subvalvular aortic stenosis are frequently masked by the findings of associated lesions. A murmur is noted within the first year of life in more than one-half of patients.[172,174] Initially, it is often considered to be secondary to a small ventricular septal defect or to be functional. The murmur becomes more typical of left ventricular outflow tract obstruction as the patients become older.[172,187] Patients with isolated subvalvular stenosis have a murmur more typical for left ventricular outflow tract obstruction. There is a systolic ejection murmur maximal at the mid left sternal border with radiation to the upper sternal borders and suprasternal notch. An ejection click is heard in only 5% of patients without associated aortic valvular stenosis.[188] An early diastolic murmur of aortic insufficiency is heard in 30 to 50% of patients.[172,173,177] In older reviews, although symptoms were reported in a high percentage of cases the incidence of symptoms was undoubtedly overestimated because of the difficulty in diagnosing mild obstruction prior to the widespread use of echocardiography (i.e., there are many children with mild obstruction who are asymptomatic). In patients with mild subaortic stenosis, symptoms of chest pain and syncope are not seen.[179]

The electrocardiogram usually is abnormal in patients with subaortic stenosis. Left ventricular hypertrophy is seen in 65 to 85% of patients, but a normal ECG is seen in occasional patients with severe obstruction.[172,174] Left ventricular hypertrophy is seen in up to 50% of patients with even mild stenosis.[179] Approximately 25% of patients have a strain pattern on the ECG. Infants are more likely to show a pattern of right ventricular hypertrophy.[172,174]

Chest radiographic findings are similar to those seen in patients with aortic valvular stenosis. Heart size usually is normal but may show mild cardiomegaly or evidence of left ventricular prominence even in patients with mild stenosis. Dilation of the ascending aorta is seen in approximately 25% of patients.[174,177]

Echocardiography

The classical m-mode echocardiographic features of subvalvular aortic stenosis are seen on a sweep from the left ventricular body to the aortic root. Left ventricular hypertrophy commensurate with the left ventricular systolic pressure is seen.[186] The left ventricular outflow tract is narrowed echocardiographically in the majority of

patients; in some patients an abnormal structure in the left ventricular outflow tract can be visualized.[189–191] In addition, the aortic valve motion is abnormal with early systolic partial closure and abnormal fluttering of the valve. This abnormal fluttering and partial closure appears to be due to turbulence distal to the subvalvular obstruction.[192]

The spatial orientation provided by two-dimensional echocardiography allows clear visualization of the subaortic stenosis and differentiation of the types of aortic stenosis.[193,194] In patients with membranous subaortic stenosis, the parasternal long axis view and apical long axis view demonstrate a thin membrane below the aortic valve extending from the ventricular septum (Fig. 79–9). In some patients, a posterior attachment of the membrane can be seen along the mitral valve.[165,195,196] With the use of multiple imaging planes and newer high-resolution ultrasound equipment, most authors feel that echocardiography is superior to angiography in the recognition and characterization of subvalvular aortic stenosis.[178,195] The severity of outflow tract obstruction, however, cannot accurately be determined solely on the appearance of the subaortic area.[165,197] Pulsed Doppler echocardiography demonstrates turbulent flow below the aortic valve, and continuous wave Doppler provides a reasonably accurate estimate of the gradient across the left ventricular outflow tract.[166,197,198] Pulsed Doppler echocardiography also demonstrates the presence of aortic insufficiency.

Cardiac Catheterization

Combined left and right heart catheterization is recommended in patients with suspected subvalvular aortic stenosis because of the high incidence of associated cardiac abnormalities. The left ventricle is entered using either the retrograde or transseptal approach. Retrograde catheterization of the ventricle usually is easier than in patients with aortic valvular stenosis, but it may be quite difficult in patients with severe subvalvular stenosis.[188] Careful withdrawal of a catheter with closely spaced sampling holes often can demonstrate a pressure gradient below the aortic valve. However, a subaortic membrane is frequently close enough to the valve that this distinction is difficult or impossible. In some patients—especially those with associated ventricular septal defect—there may be little or no gradient even with definite angiographic evidence of a membrane.[187]

The left ventricular ouflow tract is best seen using the long axial projection and elongated right anterior oblique projection.[92,93] The thin membrane in the left ventricular outflow tract may be difficult to see in some phases of the cardiac cycle. Both the appearance of the membrane and the appearance of dye trapped between the membrane and the valve must be sought carefully (Fig. 79–10). The aortic valve cusps often are thickened but have a straightened (''tenting'') rather than doming appearance in systole.[169] Thirty to 50% of patients will have evidence of aortic insufficiency on aortic root injection, and the subaortic chamber may be better seen on this injection in some patients.[172] Left ventricular hypertrophy is obvious in patients with severe stenosis. Differentiation from hypertrophic cardiomyopathy is occasionally difficult; however, patients with hypertrophic cardiomyopathy usually have asymmetric septal hypertrophy and a widely patent outflow tract.[177]

Natural History

The natural history of subvalvular aortic stenosis is clouded by previous difficulty in differentiating it from aortic valvular stenosis until the widespread use of echocardiography. Much of the natural history in infants is influenced by the high percentage of patients with associated abnormalities. Congestive heart failure and sudden death are seen in some young patients but are usually secondary to associated lesions.[172]

Subvalvular aortic stenosis is a progressive lesion in the majority of patients. In recent series, up to 75% of patients have shown an increase in gradient of 25 mm Hg or more over a 5-year period.[178] This progression appears to be more rapid than in patients with aortic valvular stenosis. Rare cases with very rapid progression of stenosis are well documented.[175,178,199] This rapid progression appears to be more common in patients with the tunnel type of

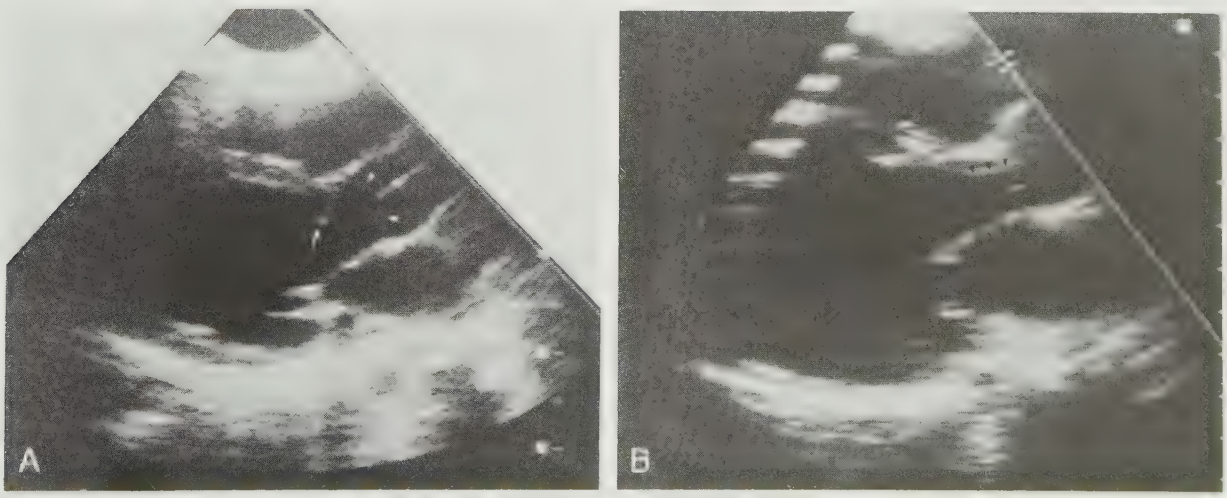

Fig. 79–9. Echocardiographic appearance of subvalvular aortic stenosis. (A) Parasternal long axis view of discrete membranous subaortic stenosis. A thin membrane (arrow) is seen extending from the septal surface of the left ventricular outflow tract immediately below the base of the aortic valve (arrowheads). (B) Parasternal long axis view of tunnel subvalvular aortic stenosis. Diffuse narrowing of left ventricular outflow tract (black arrowheads) is visible immediately below the aortic valve.

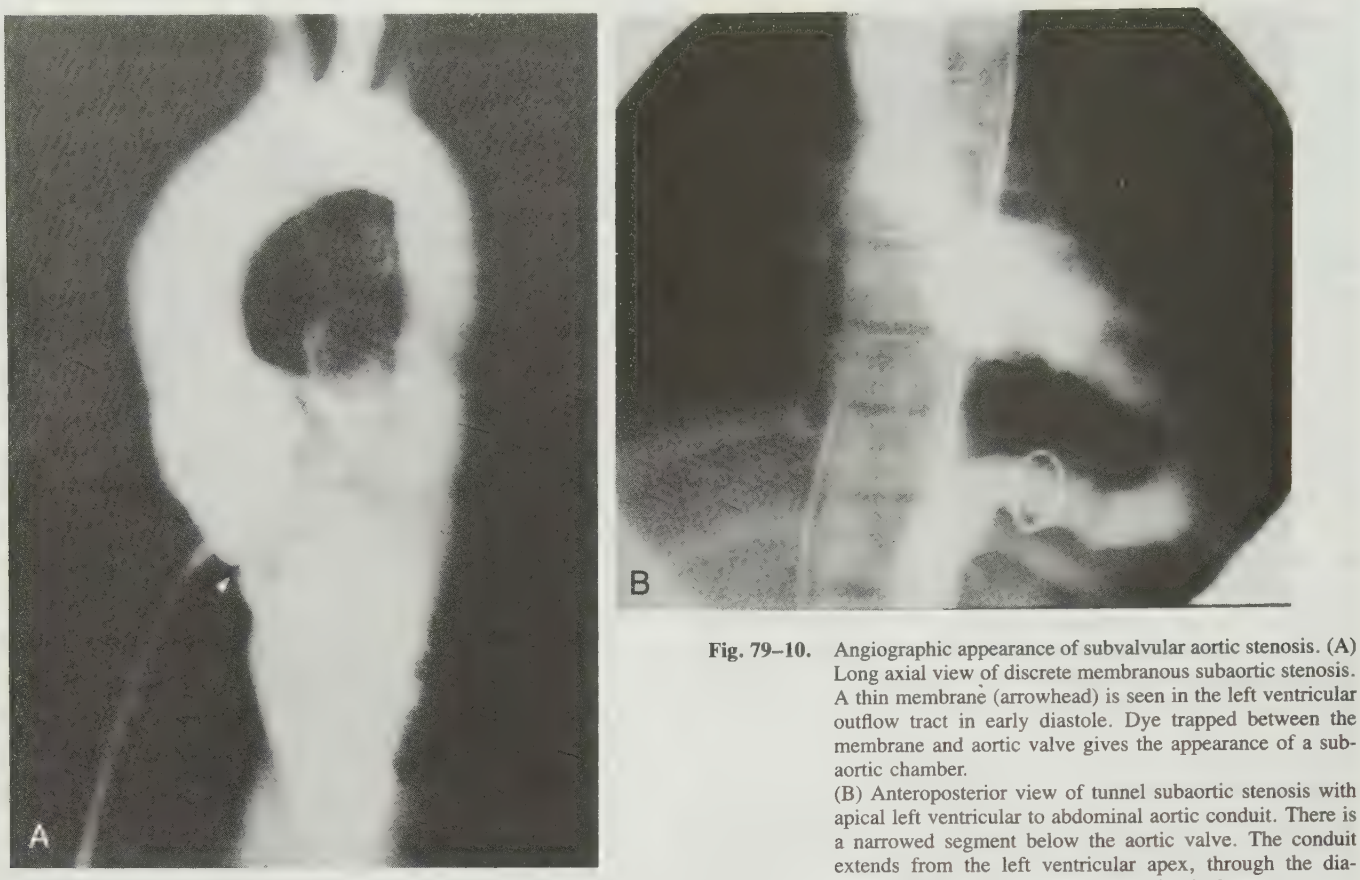

Fig. 79–10. Angiographic appearance of subvalvular aortic stenosis. (A) Long axial view of discrete membranous subaortic stenosis. A thin membrane (arrowhead) is seen in the left ventricular outflow tract in early diastole. Dye trapped between the membrane and aortic valve gives the appearance of a subaortic chamber.

subaortic stenosis. The incidence of aortic insufficiency also has been shown to increase with increasing age.[178,179] The degree of insufficiency is generally mild to moderate in pediatric patients unless the patient has had bacterial endocarditis.[173,177,179,200] The incidence of bacterial endocarditis may be as high as 13–25%.[183] Sudden death has been reported but the exact incidence is uncertain.[172]

Treatment and Followup

The surgical treatment of membranous subvalvular aortic stenosis is excision of the membrane under direct vision through the carefully retracted aortic valve using cardiopulmonary bypass.[106,177] It is important to remove as much of the membrane as possible without damaging the mitral valve or risking creation of a ventricular septal defect.[183] Patients with a thicker ridge or tunnel are more difficult to treat surgically. The obstruction is often well below the aortic valve and difficult to visualize. Involvement of the anterior leaflet of the mitral valve is common, and there is usually a great deal of ventricular hypertrophy.[174,177]

Resection of a subaortic membrane can be achieved with a low operative mortality ranging from 0 to 6%.[116,172,173] In the majority of patients, reduction of the gradient is good. In several series, 10 to 25% of patients have had residual gradients in excess of 50 mm Hg.[116,172,183] In some of these patients the membrane may have been incompletely excised. Some patients may, in fact, have had a more diffuse form of subaortic stenosis rather than the membranous form. In every series, the tunnel form of subaortic stenosis has a much worse prognosis. Operative mortality is higher. Simple myomectomy with attempted excision of thickened tissue results in a high percentage of patients with residual gradients.[172,174,177] Recent data indicate that subaortic stenosis may recur and require reoperation; surgery may also be necessary for treatment of increased aortic insufficiency, or for pacemaker placement in 10 to 20% of patients.[172,201] The left ventricle to aorta conduit or aortoventriculoplasty procedures are utilized in patients who require re-operation for stenosis.[106,132,133,135,137]

The major consideration in the management of patients with subvalvular aortic stenosis is to make an accurate diagnosis and determine when patients require surgical intervention. Because of the possibility of rather rapid progression, we routinely follow patients with definite subaortic obstruction every 6 months when they are less than 3 years of age and yearly thereafter. There is considerable concern generated by the likelihood of progression in this disorder. Generally, surgical intervention is considered justified with a smaller gradient than in patients with aortic valvular stenosis.[172,178] Certainly any patient requiring intracardiac surgery for an associated lesion who has echocardiographic evidence of a subaortic membrane should have the membrane excised at the same time. In most centers, a pressure gradient in excess of 40 to 50 mm Hg is also considered to be an indication for surgical

intervention.[106,179] Because surgical treatment of this lesion is by no means perfect, we do not routinely refer patients for surgery with lesser gradients. Approximately 25% of patients will show little or no progression over a long period of time without surgery. We feel that echocardiography and Doppler are sensitive for detecting any progression. Therefore, we prefer to follow our patients with lesser gradients carefully rather than routinely recommend operation. Patients who show development or progression of aortic insufficiency with even minimal gradients should be considered for surgical intervention.[178,179] Although percutaneous balloon dilation of subaortic stenosis has been reported in a small number of patients, this procedure has not yet gained wide acceptance.[202]

CHAPTER 80

Coarctation of the Aorta and Interrupted Aortic Arch

Mary J H Morriss
Dan G McNamara

COARCTATION OF THE AORTA

Coarctation is a term derived from the Latin verb "arctare," meaning to make tight. It is used to describe a narrowing of the aorta most commonly occurring in the thoracic descending aorta. True coarctation results from a localized thickening of the aortic media, which protrudes into the lumen of the vessel and obstructs blood flow.

Historical milestones in the recognition of coarctation of the aorta were interestingly reviewed by Jarcho in a series of articles.[1–5] Credit for description by prosection of "narrowing of the aortic conduit" is given to Johann Meckel, whose published account in 1768 postdated by 18 years his presentation before the Royal Academy of Sciences in Berlin. The slow evolution in recognition of coarctation as a clinical entity is apparent from these readings. The anomaly, now easily characterized by physical examination, is still the subject of much investigation. This chapter will address more recent observations regarding the pathogenesis, medical, and surgical management, treatment with interventional catheterization, and long-term followup of coarctation.

DEFINITION OF TERMS

Other modifiers of coarctation are used to describe variations in anatomy, age of presentation, and pathophysiology.[6] The term "adult coarctation" (often called "postductal coarctation") has been used historically to describe a short-segment abrupt narrowing located just beyond the point of insertion of the ductus arteriosus or ligamentum arteriosum. The implication is that symptoms occur only in adults. Infantile coarctation (interchangeably called "preductal coarctation") was characterized by more diffuse narrowing of a segment of the aorta plus a constrictive zone in the isthmus beyond the origin of the left subclavian artery but proximal to the ductus arteriosus. The ductus arteriosus remains patent and inserts below the coarctation, acting as a conduit to shunt blood from the pulmonary artery into the descending aorta beyond the obstruction. Other important congenital defects of the heart are also usually present.

These classifications are limiting in that they do not allow for all the variations in anatomy and because the distinction between these types is not always clear. Isolated coarctation, or a more complicated "coarctation syndrome," can be found in patients of all ages, particularly when the natural history of the defect has been altered by surgical management.

Uniformly, coarctation of the aorta results from a peculiar ridge-like thickening of the media of the aortic wall that protrudes into the lumen of the vessel from the posterior and lateral wall; an orifice eccentric in location and displaced toward the point of insertion of the ligamentum remains (Fig. 80–1).[7] This medial thickening is typical of coarctation at any age, including infancy (Fig. 80–2). Additional thickening of the intima over the medial protuberance occurs as time elapses, and contributes to further luminal narrowing. The degree of indentation of the external surface of the aorta may be minimal in comparison to the extent of the internal narrowing. The infolding of the posterior lateral aortic wall is usually just opposite the area of insertion of the vestigial ligamentum or ductus, when patent, and is best considered to be "juxtaductal" in location (Fig. 80–3). The stricture of the aorta

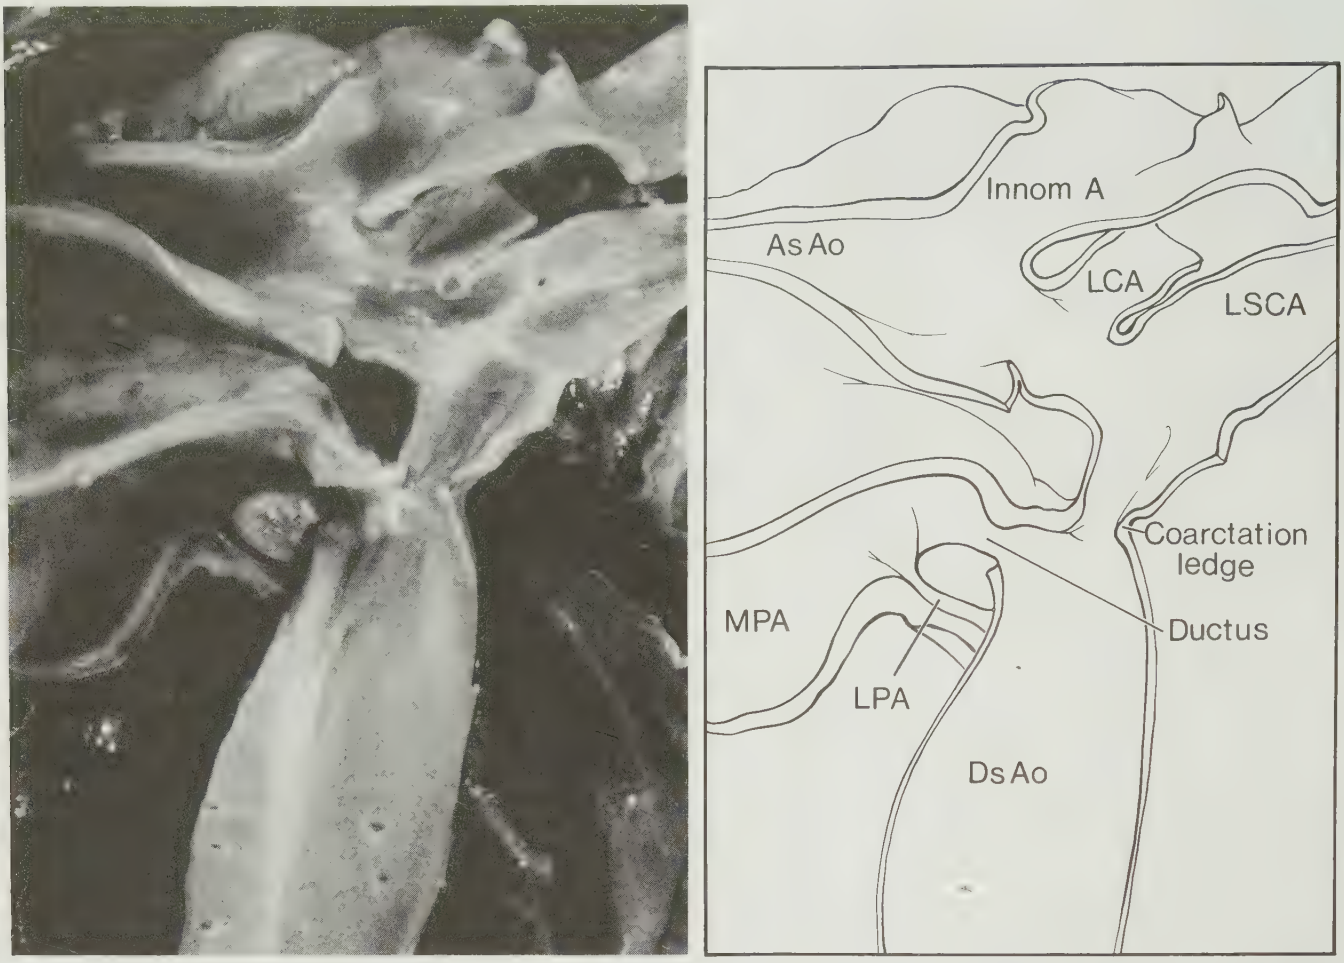

Fig. 80–1. Coarctation of the aorta; the specimen was obtained from an infant. The coarctation ledge juts into the lumen of the aorta just below the level of the left subclavian artery (LSCA). Rugations of "ductal tissue" are grossly seen on the medial wall just opposite the coarctation ledge. AsAo = ascending aorta; Innom A = innominate artery; LCA = left carotid artery; MPA = main pulmonary artery; LPA = left pulmonary artery; DsAo = descending aorta. (Specimen courtesy of Debra Kearney, M.D.)

is almost always located just beyond the origin of the left subclavian artery, although involvement of the origin of the left subclavian artery is not unusual. A longer segment narrowing, described as tubular hypoplasia of the aorta, is a combination of small diameter and abnormal length; it can involve the transverse aorta and isthmus and does not invariably produce obstruction. Most commonly, however, true tubular hypoplasia of the transverse aorta occurs with additional isthmic narrowing and stenosis (true coarctation).[8] In this context, definition of the normal aortic arch and its segments should be reviewed to avoid confusion with terminology (Fig. 80–4). Criteria for length of the segments of the aorta and diameter of the segments compared to the ascending aorta is useful in describing departures from normal.[9] The normal aorta begins at the aortic valve and changes in its direction as it ascends from a posterior inferior location to an anterior superior location, where it gives rise to its first branch, the right innominate artery. The transverse arch is that segment giving rise to the right innominate, left carotid, and left subclavian arteries. The transverse arch is usually subdivided into its distal segment between the left carotid and the left subclavian artery and the proximal segment between the innominate vessel and the left carotid artery. The isthmus of the aorta is the term reserved for the portion of the aorta between the origin of the left subclavian artery and insertion of the ductus arteriosus or ligamentum, with the descending aorta beginning just beyond the isthmic segment. Using this terminology, then, the discrete curtain lesion of coarctation is found in the isthmus of the aorta (Fig. 80–5).

Applying normal standards to infants, no defined segment of the aortic arch (proximal segment, distal segment, or isthmus) exceeds 5 mm in length. Compared with the ascending aortic diameter the relative segment diameters should be as follows: proximal aortic arch, 60%; distal aortic arch, 50%; and isthmus, 40%. It is when these conditions are not fulfilled that true segmental hypoplasia of the infant aorta is present.

ASSOCIATED MALFORMATIONS

A congenitally bicuspid aortic valve is the most frequent additional malformation occurring in patients with coarctation of the aorta. Estimates of frequency of this association have varied widely, from 13% to 85%.[10,11] In a review by Roberts[12] of 85 cases of bicuspid aortic valve, only five patients had additional coarc-

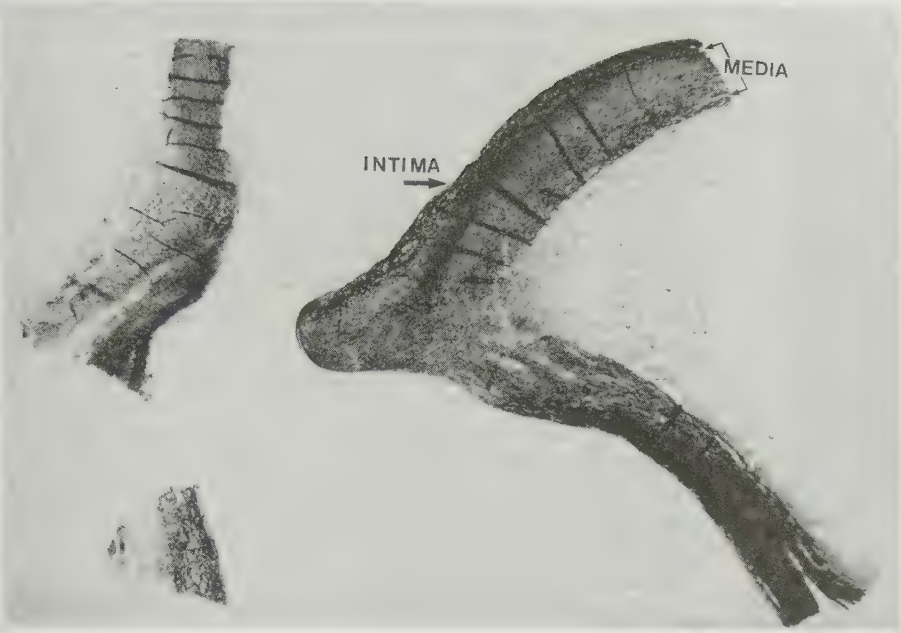

Fig. 80–2. Microscopy specimen of coarctation ledge composed primarily of media. Thin intimal covering can be seen in this section.

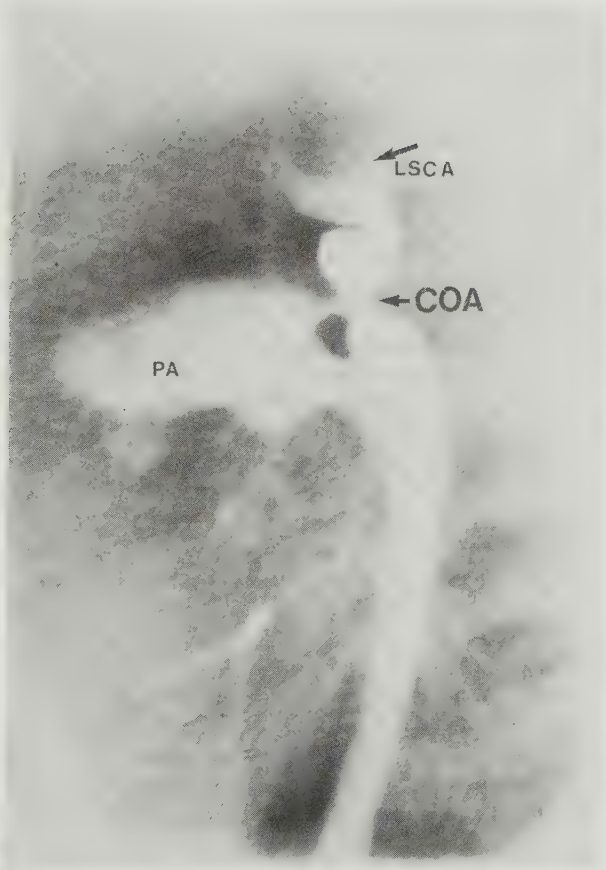

Fig. 80–3. Lateral angiogram of a 1-year-old patient with coarctation. The injection was made into the aorta above the coarctation ledge. Juxtaductal coarctation (COA) is outlined. Left-to-right ductal shunting occurs with opacification of pulmonary artery (PA). LSCA = left subclavian artery.

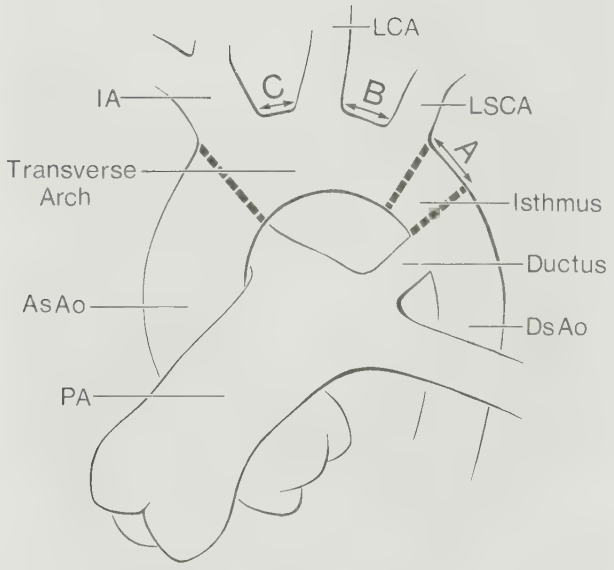

Fig. 80–4. Nomenclature for segments of the aorta (see text). PA = pulmonary artery; AsAo = ascending aorta; IA = innominate artery; LCA = left carotid artery; LSCA = left subclavian artery; DsAo = descending aorta. Portions labeled A, B, and C are measured segment lengths referred to by Moulaert which in infant aorta do not exceed 5 mm in length; these also correspond to the most common sites of arch interruption and locations for diameter measurements to interpret arch "hypoplasia." (Redrawn from Moulaert, A.J., Bruins, C.C., and Oppenheimer-Dekker, A.: Anomalies of the aortic arch and ventricular septal defects. Circulation, *53*:1011, 1976.)

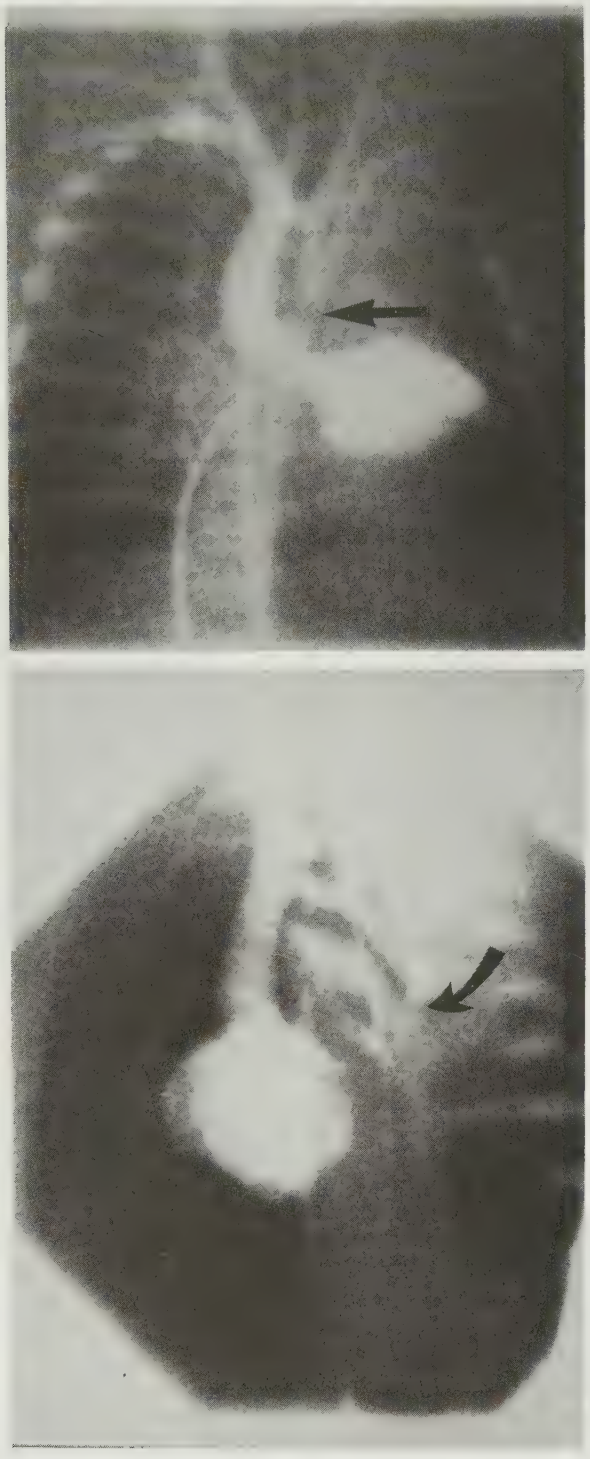

Fig. 80–5. Unusual isolated coarctation in a newborn with Ellis-van Creveld syndrome. There is hypoplasia of the transverse arch and elongation of arch segments. The isthmus is short, and a tight isthmic coarctation is identified (arrows).

tation of the aorta, attesting to the common occurrence in the adult population of isolated bicuspid aortic valve.

The exact anatomy of the bicuspid aortic valve seen in association with coarctation is a subject for continued discussion. Based on early autopsy descriptions, two types of bicuspid valves were most commonly identified[13]; 28 of 46 bicuspid valves had two cusps, often of large size with no identifiable raphe; 18 of 46 bicuspid valves were distinct in having a raphe almost invariably marking a line of fusion between the right and left coronary cusps. The relative size of the two leaflets was not emphasized. More recently, evidence has been offered that the bicuspid valve seen in association with coarctation is unique in that it is "equally bicuspid"—that is, it is more likely to have two cusps closely similar in size.[14]

Inclusion of bicuspid aortic valve makes left-sided cardiac malformations relatively common in their association with coarctation of the aorta. The additional spectrum of mitral valve anomalies found in patients whose primary diagnosis in life was coarctation is chronicled by Rosenquist.[15] A mitral valve of normal size and anatomy was found in only nine of 53 specimens examined, with an unexpected high frequency of variation in mitral valve size, restriction to the free margins of the anterior leaflet, abnormal apposition of papillary muscles, or true parachute mitral valve found in the remainder. Coexistence of multiple sites of left heart obstruction to include coarctation of the aorta constitute "Shone's syndrome."[16]

Associated intracardiac defects seem overrepresented among patients with true coarctation plus hypoplasia of the aortic arch and in fact are regarded by some to represent the "coarctation syndrome," with systemic right ventricular pressure and ductal right-to-left shunting. All types of ventricular septal defects occur with coarctation, with a frequency distribution similar to that of ventricular septal defect (VSD) alone.[17] Often, the orientation of great vessels arising from the heart with relation to the VSD, combined with additional left ventricular outflow obstruction, further allow augmentation of pulmonary flow and reduction of prograde aortic flow. In addition to the defects already mentioned, atrioventricular canal has a higher than expected incidence of associated aortic coarctation.[18] Cyanotic congenital defects of the heart may also be accompanied by coarctation,[19,20] including truncus arteriosus and transposition of the great arteries, particularly when there is overriding of the pulmonary artery and a subpulmonic VSD (Taussig-Bing anomaly).

EMBRYOLOGY

According to the theory formulated by Skoda in 1841, coarctation was thought to be a malformation that became manifest postnatally after closure of the ductus arteriosus.[21] The Skodaic theory was based on the observation that smooth muscle from the ductus extended into the aorta so that postnatal ductal constriction would place traction on the aorta and narrow the site of insertion of the ductus. This theory does not explain the location of a shelf-like protrusion of the media rising on the wall opposite from ductal insertion. In spite of agreement that ductal closure can "unmask" a coarctation lesion,[22] it is necessary to propose pathophysiology that during intrauterine development would result in the formation of a coarctation shelf lesion.

Morphologically, the ductus, like other arteries, has a wall com-

posed of intima, media, and adventitia. Essentially, the ductus is a muscular artery, as the media is recognized to consist of smooth muscle cells, and when contrasted with the aorta is deficient in elastic lamellae. Histologic study allows recognition of "ductal tissue" and an atypical extension of ductal tissue "like a sling" into the aorta is not only characteristic of coarctation but thought to be contributory to narrowing of the aorta with normal ductal closure.[8]

The occurrence of discrete coarctation in the embryologically complex area near the junction of the third, fourth, and sixth arches has led to theories that depend on blood flow in utero and the timing of insult so that a wide spectrum of conditions, from mild coarctation through interruption of the aortic arch, could result. In utero, the majority of the volume of left-sided cardiac output is distributed to the upper body, leaving only a small amount to traverse the isthmus to join the large volume of flow crossing right to left through the ductus and subsequently to the placenta. The narrow caliber of the isthmus of the aorta in the fetus and newborn infant reflects the low volume of flow through this segment prenatally.[23] The discrepancy in size between the isthmus and other portions of the aorta is not usually apparent after two months of postnatal life. Any alteration in intrauterine flow patterns that would further divert flow from the ascending aorta and its branches into the right ventricle and by way of the ductus to the descending aorta could further exaggerate the normally small caliber of the isthmus and result in true underdevelopment of this segment, which would be apparent after birth.[24] The attraction of this theory is that vessel size is proportional to blood flow and that measured dimensions of the great vessels reflect the pathophysiology.

Imprecise terminology has allowed confusion in distinguishing between underdevelopment of an aortic segment and true coarctation. The term *tubular hypoplasia* should be used to describe a long, uniformly narrow segment of the aorta variably found in the proximal or distal aortic arch or isthmus, which is not necessarily, and usually is not, obstructive; the media of the aorta in these regions is normal. In contrast, true *coarctation* results from an abnormality of the media, most commonly in the isthmic region, which produces stenosis. These abnormalities frequently coexist. It is important to recognize coarctation as a separate entity because of its obstructive nature; true tubular hypoplasia is important to recognize because of its high association with other severe congenital heart defects.

It is not easy to explain in all instances an embryologic event that would result in the usual discrete juxtaductal coarctation of the aorta without additional arch hypoplasia; however, the high incidence of associated bicuspid valve has led some authors to propose that this may be sufficient to alter left ventricular output in utero to a mild degree and allow development of the shelf lesion of coarctation in the aortic isthmus without attendant severe underdevelopment of any other segment of the aorta.

The pathogenesis of coarctation is still debated, although the many causative factors suggested could be reconciled. Altered intrauterine flow pattern, differing in degree, would contribute to prenatal arch hypoplasia and molding of the coarctation shelf. Progression in the degree of severity of coarctation may be the result of progressive intimal thickening added to the coarctation ledge. The protuberance of media into the lumen (coarctation shelf) is pulled toward the contralateral wall with ductal closure much like a cork fits into the mouth of a bottle (Fig. 80–6).

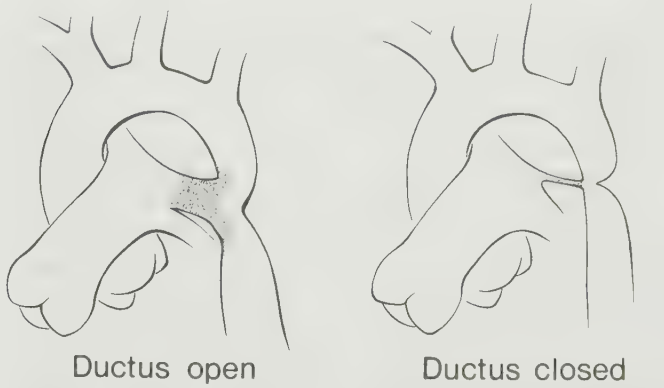

Fig. 80–6. Influence of ductal closure on coarctation shelf. The coarctation ledge becomes obstructive with ductal constriction. Stippled area represents concept of extension of ductal tissue into aortic wall (see text).

EPIDEMIOLOGY AND GENETICS

Coarctation of the aorta is not a rare defect in the spectrum of congenital heart disease. In surveys of patients recognized to have congenital heart disease (independent of cases of related bicuspid aortic valve and mitral valve prolapse), this abnormality accounts for 5 to 8% of patients. There is a striking male-to-female ratio for discrete coarctation of the aorta, with males representing over two thirds of patients in most series. The exception is that of abdominal coarctation, in which case a female preponderance is usual. In addition, the male-to-female ratio is less evident in infants with coarctation syndrome. Although it is rare to observe a true racial difference in most forms of congenital heart disease, there is some suggestion that coarctation is less common in children of Asiatic countries, who share a similar ancestral origin with North American Indian children. It is not clear if this is a matter of detection. An increase in seasonal occurrence of coarctation of the aorta with a peak incidence in September and November births has been proposed and possibly is indicative of some environmental influence.

Turner's syndrome is discussed fully in Chapter 144. Patients with the full XO Turner's syndrome with ovarian agenesis and short stature are said to have a high incidence of coarctation in 15 to 20% of cases. This is seldom true with mosaic forms of Turner's or Turner's phenotype. A rare familial pattern to coarctation has also been reported.[25]

PHYSIOLOGY

The major physiologic effect of coarctation of the aorta is to increase the afterload of the left ventricle. During ejection, the left ventricle must empty against the resistance mechanically imposed by the obstruction as well as against the increase in arterial pressure that has developed proximal to the coarctation. Consequently, systolic wall tension in the left ventricle is increased, with development of left ventricular hypertrophy. Blood pressure in the aorta and the branches of the aorta that arise above the coarctation is increased and although variable in degree, systolic hypertension above with systolic hypotension below the constricted area are present in all cases of aortic coarctation. The alterations in the arterial waveforms above and below the coarctation can be explained on the basis of differing degrees of narrowing of the aortic lumen (see Fig. 80–19). In the experimental

coarctation model well examined by Gupta and Wiggers,[26] an understanding of these changes is systematically presented. The arterial pressures are not significantly affected until the aortic lumen has been reduced by 45 to 55%. The first change seen is an increase in systolic pressure above the obstruction with a later increase in diastolic pressures above the obstruction but to a lesser degree than that of the systolic increase, allowing for progressive widening of the pulse pressure above the coarctation. Below the coarctation there is a gradual decrease in systolic pressure as well as diastolic pressure.

The greater decrease in systolic compared with diastolic pressure results in a narrow pulse pressure below the coarctation. Comparison of waveforms reveals that the pulse contour measured below the obstruction rises and falls more slowly than the pulse contour in the proximal aorta, resulting in a delayed slow upstroke, rounded broad peak, and a smooth declining slope during diastole.[27] The clinical recognition of a "delay" between radial and femoral pulses is not attributed to a delay in transmission from the aorta to the femoral artery. Rather, the tactile sensation of diminished delayed femoral pulses is explained on the basis of the slower rate of rise of the pulse wave, the difference in the timing of the peaks of these curves, and the narrow pulse pressure.

By the time the aortic lumen is moderately constricted, the femoral arterial systolic pressure no longer exceeds the aortic pressure. The constricted area serves to dampen the pulse wave as it passes through this area and the less forceful impact of the pulse waves is used to explain that the standing wave is not created downstream; the summation of pressures on the anacrotic limb of the pulse contour is prevented, resulting in the lack of systolic overshoot, which is normally recognized in a femoral waveform recording.

It is known that equivalent degrees of constriction may not be reflected by the same measurement of blood pressure elevation nor be accompanied by the same alteration in femoral pressures, owing to the development of collateral vessels. More severe hypertension and pulse discrepancy may be seen in a young child compared with that same patient who, when collateral vessels develop in later childhood, may have less hypertension and the re-appearance of palpable but diminished femoral pulses. Collateral vessels bypass the coarctation and channel flow to the lower body. The collaterals primarily arise from branches of the subclavian vessels and involve internal mammary arteries, intercostal arteries, and spinal arteries (Fig. 80–7).[28]

It is an oversimplification to attribute the hypertension that is seen with coarctation of the aorta solely to mechanical obstruction. Equally important to the degree of hypertension is the reduced distensibility of the aorta and the capacity of the vascular bed proximal to the coarctation. Additional theories implicating a resetting of baroreceptors in the aortic arch[29] and the possible contribution of a renal factor stimulated by decreased renal blood flow[30] are offered. There is no consistent evidence of a functional abnormality of the kidneys in coarctation, and determinations of peripheral plasma renin activity give conflicting results about whether an additional mechanism for production of hypertension involves the renin-angiotensin system.[31] It can be safely stated that renal factors are less important in the young patient with coarctation.

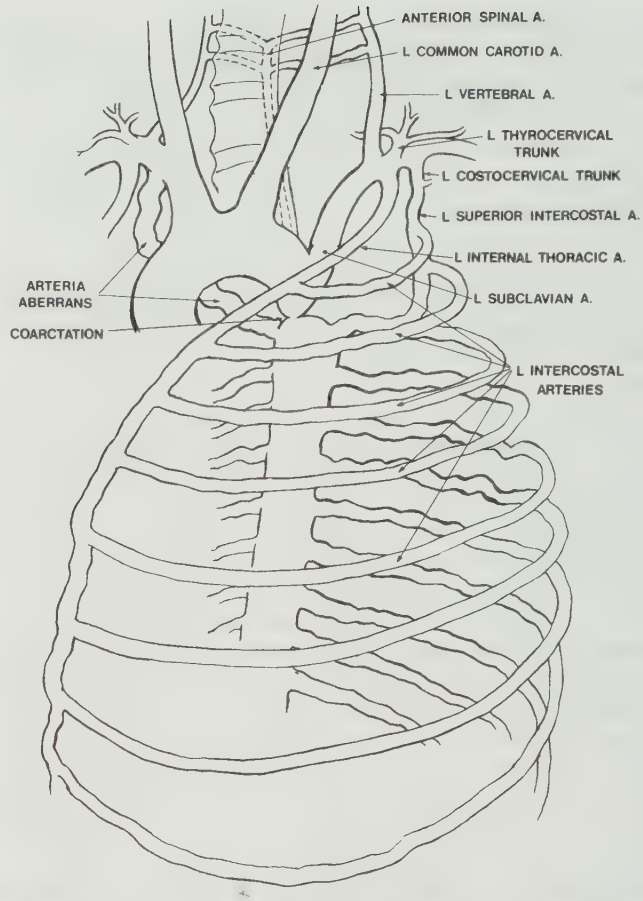

Fig. 80–7. Collateral circulation in aortic coarctation. The primary source of collaterals is from the subclavian artery via three branches: thyrocervical trunk, costocervical trunk, and internal thoracic arteries. Intercostal arteries (fourth and below) communicate directly with the aorta beyond the coarctation as well as with the internal thoracic artery and are responsible for rib-notching. (Intercostals 1 to 3 join superior intercostal artery, which in turn connects with aorta.) The anterior spinal artery receives vertebral artery communications and is involved in collateral flow to bypass the coarctation. The most constant collateral seems to be the large arteria aberrans.

CLINICAL FEATURES

The discussion of clinical features will be divided into two parts: patients who present past infancy (the more common occurrence), followed by coarctation syndrome in infancy. Clinical manifestations in both groups depend on the association of coarctation with other defects but the unique effects of coarctation of the aorta on the circulation will be emphasized.

Coarctation Past Infancy

Clinical recognition of coarctation should be obvious when blood pressure readings are obtained from all four extremities; hypertension above the obstruction and decreased blood pressure below the obstruction are the hallmarks of diagnosis. Most individuals with isolated coarctation of the aorta have no cardiac symptoms. Minor complaints of cold feet and leg cramps are seemingly volunteered more often from observant parents; however, the frequency with which these complaints may be elicited by direct inquiry even from patients without coarctation make their rele-

vance uncertain. An actual history of claudication is rare, but when it is present and a complaint of sharp pain in the lower extremities is said to limit exercise, the diagnosis of abdominal coarctation should be considered with knowledge that collateral circulation is not as easily established in the abdomen. Paresthesia, pain, and muscle weakness may occur in the lower extremities, but rather than being reflective of poor blood flow, may actually result from a dilated and tortuous anterior spinal artery compressing the spinal cord directly or one of its branches impinging upon a nerve root exiting the vertebral canal. Nose bleeds and headaches are additional nonspecific symptoms accompanying coarctation of the aorta. Unilateral headaches, particularly of unusual severity, are rarely indicative of cerebral aneurysm in association with coarctation but should prompt a full neurologic evaluation. Older clinical reports mentioned plethora and flushing of the face as well as delayed healing of lower extremity wounds as accompaniments of aortic coarctation.

Physical Examination

The outstanding physical finding is that of striking inequality in the strength of upper extremity pulses compared with the small volume or absent lower extremity pulses. This is further substantiated by blood pressure measurements indicating hypertension in the upper extremities while lower extremity pressures are difficult or impossible to record. Hypertension, though invariably present, may not directly reflect the severity of obstruction and may not be extreme. A body build commonly seen in adolescence features a sturdy, well-developed upper torso in contrast to a thinner lower body with trim hips and legs. The characteristic appearance of patients with Turner's syndrome—short stature, webbed neck, and shield chest—presents another clinical profile that should raise the question of co-existence of coarctation of the aorta. Funduscopic examination has revealed a peculiar "corkscrew" appearance to retinal arteries in a pattern unlike hypertensive retinopathy (Fig. 80–8).

Unequal blood pressures between the two arms may be the result of the peculiar position of one or both subclavian arteries in relation to the coarctation. A right arm pressure higher than the left arm pressure suggests that the coarctation is proximal to the left subclavian artery or involves the origin of the left subclavian artery. When left arm pressures are higher than right in the presence of coarctation, an anomalous origin of the right subclavian artery arising beyond the coarctation may be the explanation. The rare occurrence of origin of both subclavian arteries in the low-pressure zone beyond the coarctation makes clinical recognition of coarctation from blood pressure measurements difficult, although palpation of bounding carotid pulses contrasting with weak femoral pulses could suggest the diagnosis of coarctation to the astute clinician.

Examination of the patient with coarctation of the aorta should be systematically performed with an attempt to explain the auscultatory findings rather than with the prejudice that a particular murmur is characteristic of coarctation. A murmur may be generated from the coarctation itself and would serve as evidence that atresia of the lumen of the aorta is not present. This murmur is best heard in the auscultatory areas corresponding to the thoracic location of the coarctation (the left infraclavicular area, axilla, and posteriorly over the left chest medial to the scapula). The murmur sometimes peaks late in systole and extends into diastole when a persistent coarctation gradient is present. Continuous murmurs generated at the site of distal connection of collateral vessels may also be present throughout the anterior and posterior chest. Particularly when detected in the left chest, these murmurs could be confused with a murmur originating from the area of coarctation. Occasionally, with severe coarctation and low cardiac output state or with complete atresia of the lumen, a murmur is absent. Presence of an aortic ejection click and an ejection murmur in the aortic area should make the clinician suspicious of an additional bicuspid aortic valve with aortic stenosis. The murmur of aortic insufficiency may be present as well and lead to additional concern about an abnormal aortic valve. A thrill at the right upper sternal border may be further evidence of aortic valve stenosis. However,

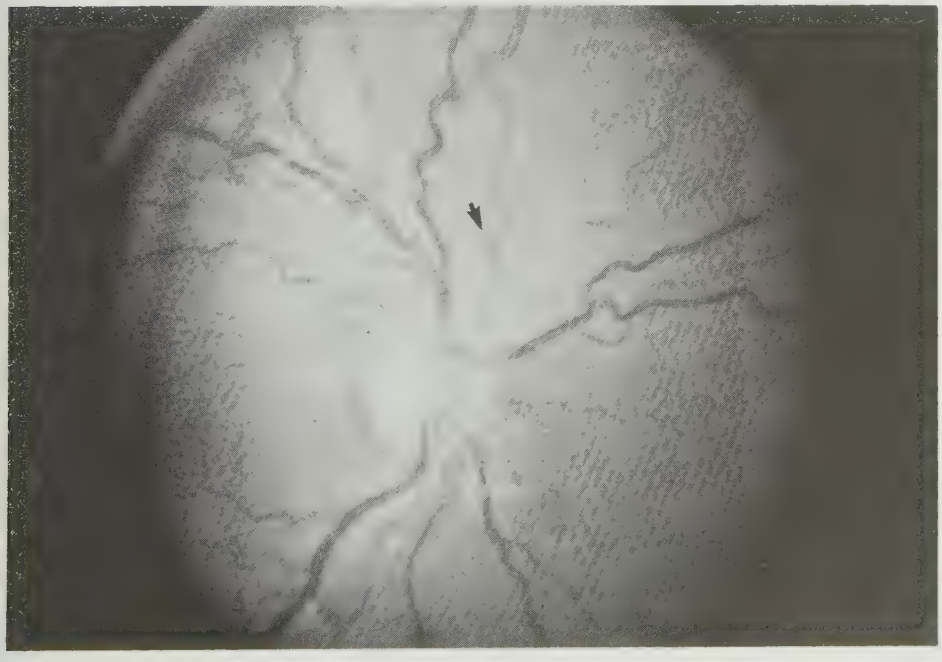

Fig. 80–8. Eyeground in a 12-year-old boy with coarctation. True arteries emerging from optic disk are more tortuous with "corkscrew" vessel shown (arrow). Pattern is different from hypertensive retinopathy at older age. Larger, darker vessels are veins.

a thrill with prominent pulsations in the supersternal notch and carotids can be present with coarctation of the aorta alone. Additional diastolic murmurs over the left axilla and at the apex of the heart could be evidence of diastolic flow across the coarctation but additionally would raise the suspicion of turbulent diastolic mitral flow associated with mitral valve abnormalities.

The presence of pulsating intercostal arteries as a clinical finding is a function of age. Palpable or visible collaterals in the interscapular region are rare in childhood and often, because of early elective surgery, do not develop. Forceful arterial pulsations visible in the neck can be present at a young age.

Simultaneous palpation of brachial and femoral vessels is helpful. In the presence of mild coarctation or with well-developed collaterals, femoral pulses can be felt. If simultaneous palpation of upper and lower extremity pulses is not conducted with recognition of the apparent delay in femoral pulses, mild coarctation may be missed. This sign can be subtle, however, and the inexperienced examiner who fails to measure pressures is likely to miss cases of mild coarctation. The first heart sound is generally normal. It can be followed by a high-frequency systolic ejection click when bicuspid aortic valve is present or if there is significant dilation of the aortic root in the presence of a normal tricuspid aortic valve. The second heart sound with isolated coarctation is usually characterized by normal respiratory variation, but the aortic component may be increased in intensity with a "ringing" quality due to the systemic hypertension.

Fig. 80–9. AP chest film from a 12-year-old boy. Rib-notching is seen best on the undersurface of right sixth and eighth posterior ribs and left fourth and eighth posterior ribs (arrows). "3 sign" (see text) is also apparent.

Electrocardiogram

Even in the presence of significant aortic coarctation, the electrocardiogram (ECG) is often normal in children. One expected change is increased voltage in the left precordial leads. True left ventricular hypertrophy is apparent with more severe or longer standing coarctation. Electrocardiographic evidence of right bundle branch block is found in approximately 50% of adults and older children and is said to reflect a stage in progression from neonatal right ventricular hypertrophy.[32]

Exercise electrocardiography may unmask ST segment and T wave changes reflective of ischemia; however, a normal exercise effort and electrocardiographic recording during exercise are not unusual.

Chest Roentgenography

Typically, the radiologic examination of an older child with coarctation shows normal heart size; less frequently the heart is mildly enlarged with a left ventricular contour (Fig. 80–9). Pulmonary vascular markings are normal unless there is an associated intracardiac shunt or manifest left ventricular failure. A dilated ascending aorta visible to the right of the sternum may accompany coarctation of the aorta even in an absence of additional aortic valve disease. The aortic knob may be inconspicuous or prominent. In some patients there is radiographic evidence of pre- and post-stenotic dilation seen as a double aortic curve, referred to as the "3 sign," along the left paramediastinal shadow in the AP view. The pre- and post-stenotic dilation is exhibited as a mirror image to that described when barium in the esophagus outlines the dilation above and below the coarcted area referred as the "E-sign" (or "reversed 3 sign"). The left anterior oblique projection may be used to enhance recognition of the post-stenotic dilation just below the level of coarctation as it produces anterior displacement of the barium-filled esophagus.

Rib-notching is practically pathognomonic of thoracic coarctation of the aorta (see Chapter 44, Fig. 44–26).[33] The incidence of rib notching increases with age because erosion of the ribs by the dilated intercostal collateral vessels progresses slowly. The erosion, or scalloping, of the undersurface of the ribs (technically in the costal grooves) is most commonly seen bilaterally in the fourth to ninth posterior ribs.[28] Unilateral rib-notching is found when one subclavian artery arises below the coarctation in the low-pressure zone with sparse development of collaterals on that side. Retrosternal scalloping by displaced and enlarged collaterals is an analogous process seen on the lateral chest film. Rib-notching occurs in 70% of patients aged 6 to 41 years and in the majority of patients over age 20 years. It is extremely rare to detect rib-notching in infancy. Rib-notching below age 5 is uncommon, although in one study it was visible in 14% of patients between 1 and 4 years of age.[34]

Echocardiogram

The clinical diagnosis of coarctation of the aorta is easier to make than the echocardiographic diagnosis. The role of M-mode echocardiography in this condition is limited to possible recognition of bicuspid aortic valve as well as estimations of left ventricular wall thickness and shortening fraction. Recognition of bicuspid aortic valve accompanying coarctation is not available with 100% accuracy even when a technically satisfactory view of the aortic root and aortic valve motion is available.[35] M-mode computation of an abnormal "eccentricity index" was used to describe the eccentric location of the point of diastolic coaptation that often accompanies bicuspid aortic valve closure, although

"equally bicuspid" valves may be difficult to identify by this method. Left ventricular wall thickness can be measured and is reflective of increased afterload. A formula used to estimate left ventricular pressure is useful in this lesion, analogous to its use in estimating left ventricular pressure with aortic stenosis.[36] This formula is expressed as:

$$\text{LV systolic pressure (mm Hg)} = \frac{225 \text{ mm Hg} \times \text{LV end systolic wall thickness (mm)}}{\text{LV end systolic dimension (mm)}}$$

Two-dimensional echocardiography from the usual echocardiographic windows on the thorax again gives evidence of left ventricular measurements reflecting increased afterload. Imaging of the region of the coarctation, however, is more difficult and best sought from the suprasternal and high left parasternal approaches (Fig. 80–10).[37] The difficulties in examining the aorta throughout its course have been described by knowledgeable echocardiographers. A particularly high level of skill is necessary to view the area of origin of the left subclavian artery and descending aorta to look for the usual location of coarctation. The suprasternal notch imaging requires support of the shoulders and hyperextension of the neck with attendant discomfort to the patient, rendering these studies difficult in an unsedated frightened child. It is frequently necessary to sedate young infants for this procedure. The particular utility of these views is increased when imaging can be coupled with Doppler echocardiography. The major justification of the effort and time required to obtain echocardiographic studies is to have additional confirmation that the coarctation is indeed in the usual location, which can eliminate the need for catheterization and permit confident recommendation to the surgeon planning a traditional incision for coarctation repair. Using the segmental approach to echocardiography, it is important to look at mitral valve anatomy, as well as to measure left ventricular wall thickness and shortening fraction and to view the left ventricular outflow tract looking for additional sites of obstruction. The descending aorta can be imaged in the long axis view in the abdomen with reduced pulsations generally observed in cases of coarctation of the aorta.

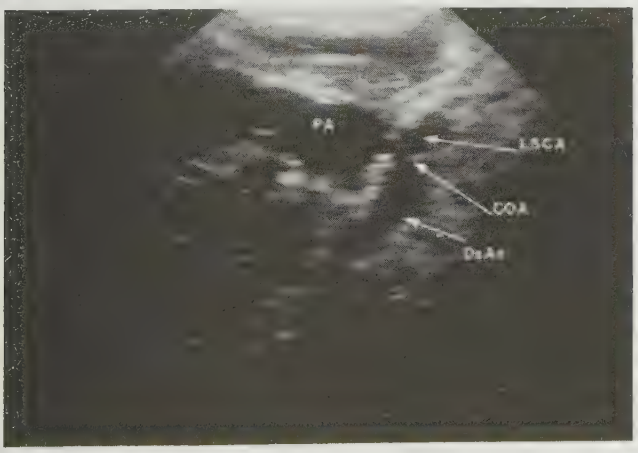

Fig. 80–10. 2-Dimensional echocardiography of a typical coarctation viewed from the high left sagittal plane. The posterior coarctation ledge (COA) is visualized beyond the origin of the left subclavian artery (LSCA) and oriented toward the ductus arteriosus, which remains patent. DsAo = descending aorta; PA = pulmonary artery.

With pulsed Doppler echocardiography, the sample volume can be placed under image direction in the area just above the coarctation site. One will find a typical pattern of diastolic runoff proximal to the coarctation caused by the persistent gradient across the coarctation in diastole. As the sample volume is moved across the area of coarctation into the descending aorta, there is a rapid increase in systolic flow velocity, which usually exceeds the Nyquist level for pulsed Doppler. A continuous-wave Doppler study can then be performed with a probe directed in the same manner across the coarctation. The continuous-wave Doppler signal (Fig. 80–11) across the area of coarctation is unique in revealing two types of flow: one with a low velocity reflecting flow through the area above the coarctation and the other a high velocity outer envelope generated by rapid velocity flow through the narrow area.

Two-dimensional echocardiography has also improved the recognition of bicuspid aortic valve, though a confident diagnosis may not always be made.[38] Since coarctation necessitates endocarditis prophylaxis indefinitely, the recognition of a bicuspid valve that functions well may not be of considerable importance. The necessity of inspecting the aortic valve in systole as well as in diastole is emphasized with the inability of the leaflets of the bicuspid valve to open completely in systole, giving a fish-mouth appearance to the opened aortic valve. The coapted leaflets in diastole may transcribe a single line of closure across the aortic root and occasionally, the position of the raphe can also be seen. The certainty with which this diagnosis can be made by echocardiography depends on the quality of image obtained as well as the experience of the echocardiographer. The high success of detection reported in the literature may not be easy for every center to reproduce.[39]

Magnetic Resonance Imaging

The role of magnetic resonance imaging (MRI) in prospective identification and followup of patients with coarctation of the aorta is not yet defined, but new reports attest that this technique allows satisfactory visualization of the coarctation area (Fig. 80–12).[40] In young children, sedation must be used for MRI. Comparing MRI and other techniques with respect to the cost, patient risk, and operator time, it would seem that echocardiography is still superior[41]; however, the confidence of diagnosis may be greater with the actual imaging available for inspection after MRI. If it has been decided during the management of the patient that catheterization is indicated, MRI evaluation would not be necessary. Clinical applications of MRI are discussed in Chapter 51. The utility of MRI may be its use in the followup of patients with coarctation to screen for distortion of the aorta after balloon dilatation, to identify aneurysm formation at an early stage, and to allow serial measurements of aneurysms that are recognized after surgical repair.[42] As usual, patients are disqualified from having an MRI study safely performed if they have a pacemaker and wires in place or if metallic clips have been previously placed in the thorax. The usual stainless steel sternotomy wires present in patients with coarctation who have had additional lesions approached by way of an anterior thoracotomy do not disqualify a patient from having an MRI study.

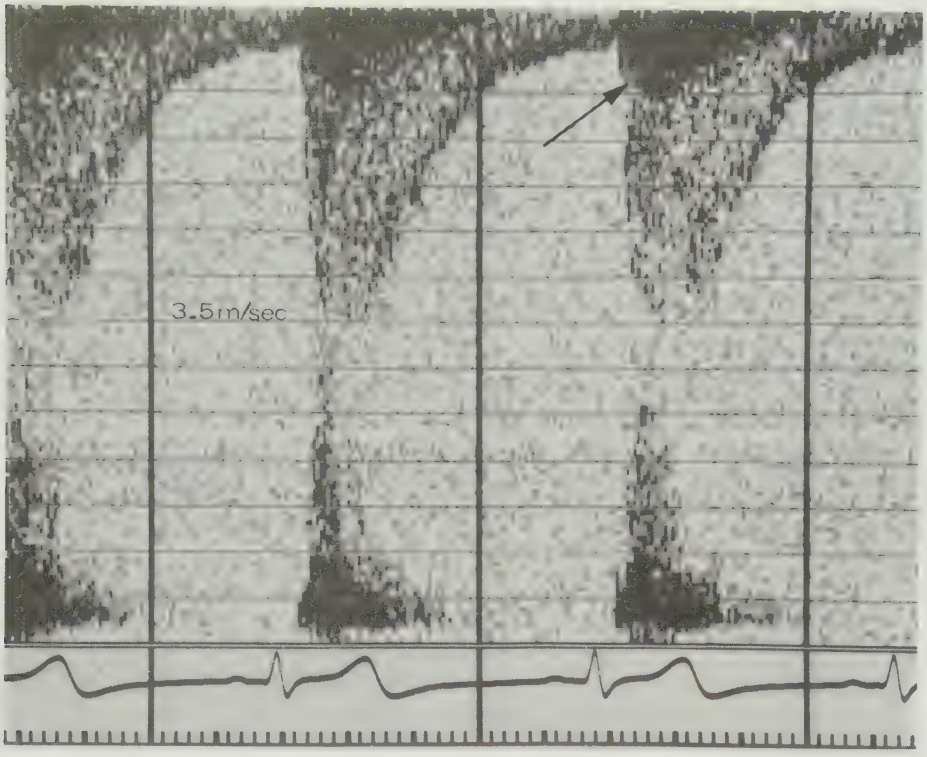

Fig. 80–11. Continuous-wave Doppler flow pattern obtained from a patient with aortic coarctation. High-velocity (3.5 m/sec) outer envelope represents flow moving through coarcted segment. Lower velocity, dense inner envelope (arrow) represents flow traveling at a lower velocity in the aorta, above the obstruction.

Fig. 80–12. Magnetic resonance imaging (MRI), parasagittal T_1, weighted image through thoracic aorta (similar to lateral view angiogram) in a 4-year-old boy. Findings were interpreted as dilation of the ascending aorta, narrowing of the transverse arch, and a "web coarctation" represented by increased signal intensity across the lumen of the aorta immediately beyond the origin of the left subclavian artery. Complete atresia of the lumen is suspected based on additional Doppler studies.

Cardiac Catheterization and Angiography

The role of catheterization in evaluating patients with isolated coarctation has been variously described as either "nonessential," "required for definition of anatomy," or more recently, "therapeutic." When the precise diagnosis of coarctation and associated lesions can be accurately and confidently made, surgery can be scheduled without catheterization. It is possible that preoperative recognition of severe hypoplasia of the aorta in addition to coarctation might influence postponement of operation although most variations in coarctation anatomy can be successfully managed by the surgeon at the time of inspection. Concern that the coarctation might be in an atypical location or that coarctation sites may be multiple may impose enough doubt on the cardiologist that catheterization is performed. In particular, catheterization is useful in cases where there is absence of rib-notching, there is an inability to confidently image the coarctation on echocardiography, and when important associated defects cannot be definitely excluded or evaluated by noninvasive techniques. Catheterization is sometimes justified by the need to determine if there are "adequate collaterals" for surgery. This position might be tenable if rib-notching is unexpectedly absent in the older patient, or if reoperation for coarctation is projected and knowledge of collateralization will influence surgical perfusion techniques.

When catheterization is performed, it should consist of complete right and left heart catheterization. The feasibility of a prograde approach to the left heart has been improved with wider application of the transseptal method for entering the left heart in cases without a patent foramen ovale (Fig. 80–13). With a prograde left heart study, the aortic valve can and should be crossed from the left ventricle with a balloon catheter to allow angiography of the aorta and a withdrawal record from the aorta to the left ventricle to search for coexistent aortic valve stenosis. The retrograde arterial

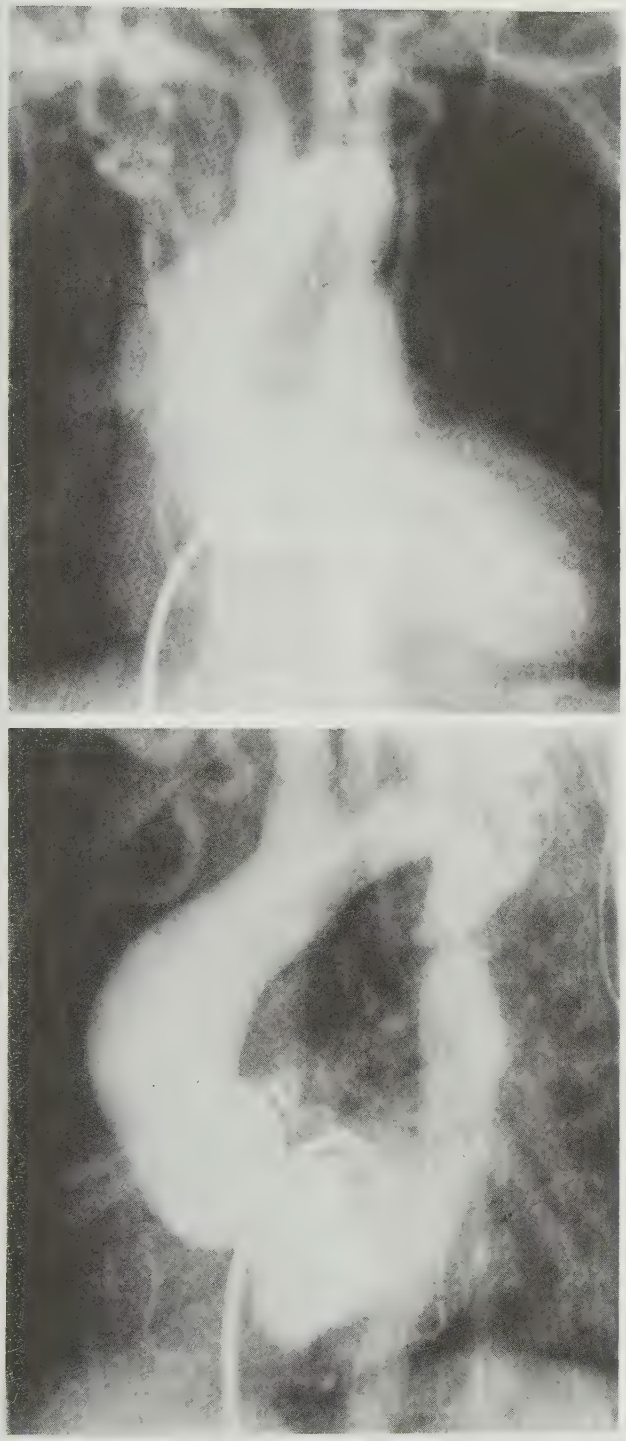

Fig. 80–13. Coarctation of aorta-LV angiogram in an 8-year-old boy. Dilation of the ascending aorta and well-developed collateral circulation are apparent in AP (top) and LAT (bottom) cine frames. The tortuosity of the aorta and its course make echocardiographic imaging difficult. The left ventricle was entered using a transseptal method.

approach from the femoral artery can be carefully done and is not considered to be inadvisable because of risk. However, it is difficult to enter the femoral artery in some cases because of the decreased femoral pulses. Techniques of balloon dilatation have demonstrated not only the ability to pass a catheter past the stenosis but also the safety of temporary occlusion of the coarctation lumen. The catheterization should be complete in the exclusion of other defects. Pressure tracings obtained from above the coarctation typically show elevated systolic, diastolic, and mean pressures with a widened pulse pressure (see Fig. 80–19B). Tracings from below the coarctation area appear damped, with low systolic pressures and narrow pulse pressure. Severe proximal obstruction at the aortic valve may mask the pressure gradient at the coarctation site.

Angiography with injections into the left ventricle and the aorta proximal to the coarctation are useful in recognizing associated defects demonstrating origin of arch vessels, viewing development of collateral vessels, and outlining the definitive anatomy of the coarctation segment.

Coarctation Syndrome In Infancy

Isolated discrete coarctation of the aorta is uncommonly recognized in the neonatal period.[49,50] Coarctation in infancy is often part of a more complex spectrum of heart disease producing recognizable heart failure or even catastrophic illness.[51] In "coarctation syndrome," a diffuse hypoplasia of the aorta is found in addition to the actual coarctation lesion, isthmic in location, that produces obstruction. Usually, other defects are present, commonly ventricular septal defect (VSD), resulting in systemic right ventricular pressure and flow reversal from right to left through the ductus arteriosus. Early age at presentation, difficulties in management, and a less favorable outcome further distinguish this entity from discrete coarctation in the older patient.

Additional diagnostic confusion results from the fact that some degree of narrowing of the transverse aorta and isthmus occurs in the normal infant without producing obstruction. Pulmonary hypertension occurring from any cause, particularly secondary to lung disease, allows right-to-left shunting through a persistently patent ductus arteriosus, which mimics the flow patterns seen with true infantile aortic coarctation. Several methods for measurement of the aorta have been proposed to distinguish normal tapering of the aorta from true hypoplasia (with a uniformly narrow but nonobstructive segment) from actual segmental constriction characteristic of coarctation stenosis. Taussig stated that the isthmus should not be considered to be abnormal unless it narrowed to the width of one of the carotid arteries.[6] Moulaert and colleagues concluded that the diameter at the isthmus had to fall below 40% of the diameter of the ascending aorta in order to identify important isthmic underdevelopment[9]; additional criteria for abnormal isthmic length were added. Sinha et al.[52] used autopsy and angiographic measurements to describe underdevelopment of the transverse aortic arch delineating it as a separate entity from isthmic coarctation. The findings that hypoplasia of the aorta, abnormally rapid tapering of the aortic arch, and localized coarctation are consistently present in the majority of infants ill with coarctation are supported by morphometric echocardiographic measurements.[24] The frequent association of other important intracardiac defects may further help to distinguish patients with true coarctation syndrome from ill newborns who have the normal degree

of isthmic narrowing but right-to-left ductal shunting caused by pulmonary hypertension. The rarity with which isolated coarctation, with normal aortic arch development and no additional defect, produces congestive failure in infancy has been emphasized in numerous reports.[49,51,52]

Hemodynamic disturbances in an infant with coarctation are variable but easily understood when consideration is given to the site and severity of aortic obstruction, as well as the influence of associated defects and the contribution of the patency and direction of flow in the ductus.[53]

When the coarctation ledge occurs as an isolated lesion proximal to the insertion of the ductus, the intrauterine flow patterns have not been altered to an extent that stimulus for development of collateral vessels in utero existed. A critical resistance to left ventricular emptying is imposed only after birth, when the ductus closes (see Fig. 80–6), runoff into the lower resistance pulmonary bed is abolished, and severe left-sided congestive heart failure occurs. This results in the clinical presentation of an infant in respiratory distress with severe cardiac failure. The newborn is recognized to have audible rales, gallop rhythm, hepatomegaly, peripheral edema, and a pulse discrepancy that has become apparent with ductal constriction. Because of the severe impairment of cardiac output, a murmur may not be detected until improved cardiac output has been achieved with treatment of the heart failure and reversal of shock.

If the hemodynamic pattern is altered to allow right-to-left ductal shunting there is a provision for clinical observation of differential cyanosis. The ascending aorta and its branches are supplied by fully saturated blood from the left ventricle whereas branches of the aorta below the coarctation are supplied from the pulmonary artery by way of the ductus, allowing a demarcation in color with cyanosis of the lower body compared to the upper body. This clinical impression can be substantiated by measuring a higher saturation of blood obtained from a right radial artery compared to a lower saturation obtained from the umbilical artery catheter below the coarctation. In the presence of an intracardiac left-to-right shunt, the pulmonary artery saturations may be abnormally high so that a measurable difference in saturations between upper and lower body is not as great. The reverse is also true in that with an intracardiac right-to-left shunt, upper extremity saturations may be lower and again not too dissimilar from the level of desaturation obtained from sampling below the coarctation site, although both will be decreased. Clinical recognition is further hampered by normally present acrocyanosis in response to temperature changes. Generalized cyanosis with circulatory shock in the very ill infant with coarctation of the aorta may render an evaluation of differential cyanosis more difficult. When the ductus is widely patent in an infant with coarctation, obvious clinical symptoms may not be present. However, spasmodic attacks of ashen color, fretfulness, and dyspnea may be seen with ductal closure, and may rapidly improve with ductal relaxation. These clinical presentations may be greatly altered when additional cardiac defects are present. The patient may have profound cyanosis apparent if transposition of the great vessels coexists with coarctation and ductus. In these infants, "reverse" differential cyanosis may occur, with the upper body bluer and the lower body pinker. The expected occurrence of a large ventricular septal defect in infants with coarctation syndrome may result in a presentation more typical for a large left-to-right shunt, with attendant difficulty in establishing the association of a coexistent coarctation when the ductus is widely patent.

In an infant with coarctation who has heart failure in infancy, suspicion of associated defects should be high. A less favorable response to medical therapy is recognized in this group, prompting early surgical treatment. The most important point to emphasize is the frequent anatomic and physiologic complexity of coarctation lesion in the infant age group.

The ECG of infants with coarctation of the aorta is often abnormal and usually reflects coexistent anatomic defects.[32] Isolated coarctation of the aorta in the neonate usually is accompanied by electrocardiographic evidence of right ventricular hypertrophy or right bundle branch block. Left ventricular hypertrophy and/or left ventricular strain is uncommonly seen in the neonate (Fig. 80–15), although left ventricular strain, in itself, may prompt earlier surgical management because left ventricular strain reflects the hemodynamic state of severe increase in afterload acutely imposed on the left ventricle with ductal closure. The echocardiogram in infants with congestive heart failure can show a marked increase in left ventricular wall thickness immediately after birth. Evidence of a dilated, poorly contracting left ventricle raises the question of cardiomyopathy or possible endocardial fibroelastosis; however, markedly severe left ventricular dysfunction as assessed by echocardiographic measurements may be found in the infant with coarctation of the aorta who has complete reversal of these findings after relief of the obstruction. Chest roentgenograms are altered by associated defects so that increased pulmonary vascular markings are seen with a left-to-right shunt or venous congestion may be found due to severe coarctation alone or associated left heart obstructive lesions. Rib-notching is rare in infants but has occasionally been reported when severe functional obstruction is present in utero.

Cardiac catheterization is undertaken at increased risk in the moribund infant with coarctation. When noninvasive recognition of the components of coarctation syndrome can be reliably defined with the adjunct of echocardiography, direct recommendation for surgical repair of coarctation of the aorta and either pulmonary artery banding or closure of a VSD, if necessary, can be a lifesaving approach. The success of balloon angioplasty for coarctation of the aorta in a sick infant continues to be debated and will be further discussed.[54,55]

Systemic hypertension rarely justifies surgery in infancy unless it is accompanied by severe left ventricular failure. No absolute level of hypertension has been published as being the single indication for surgery; the natural history with development of collateral vessels and a decrease in degree of hypertension supports the opinion that elective surgery for isolated coarctation in infancy is unwise if medical management is successful.

Surgical treatment of coarctation in an infant was first reported by Kirklin et al. in 1952.[56] In an infant presenting with congestive heart failure, the likelihood of associated important congenital heart disease is high; 80% have additional severe congenital heart disease. Poor response to medical management alone is the rule,[57] and in spite of the known high surgical mortality rate in infants under age 6 weeks (45%), mortality without surgery is reportedly higher (86%).[49] In our institution, infants with complex coarctation are offered immediate operation, consisting of relief of aortic obstruction, and we add pulmonary artery banding if a coexistent VSD is large, complex, or multiple.[58,59] Another approach is to

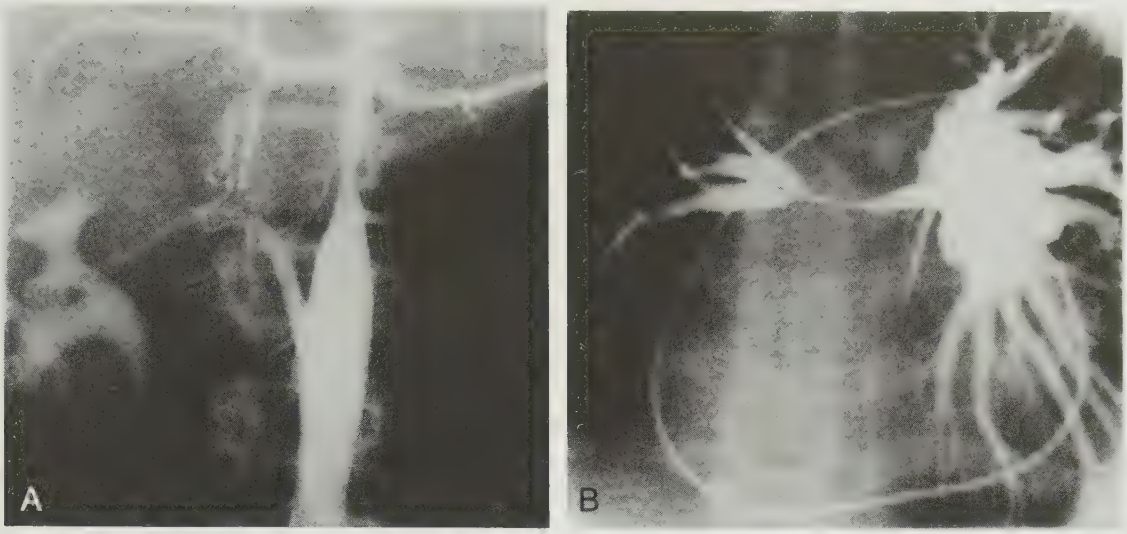

Fig. 80–14. Takayasu's arteritis in a 13-year-old girl. (A) Abdominal aortic coarctation with hourglass deformity of aorta at level of L_1. Right renal artery is stenotic. The left renal artery is not visualized owing to previous implantation of left kidney into pelvis. (B) Arteritis also affects the right pulmonary artery (RPA). Long area of severe RPA stenosis is visualized on AP angiogram with injection into main pulmonary artery.

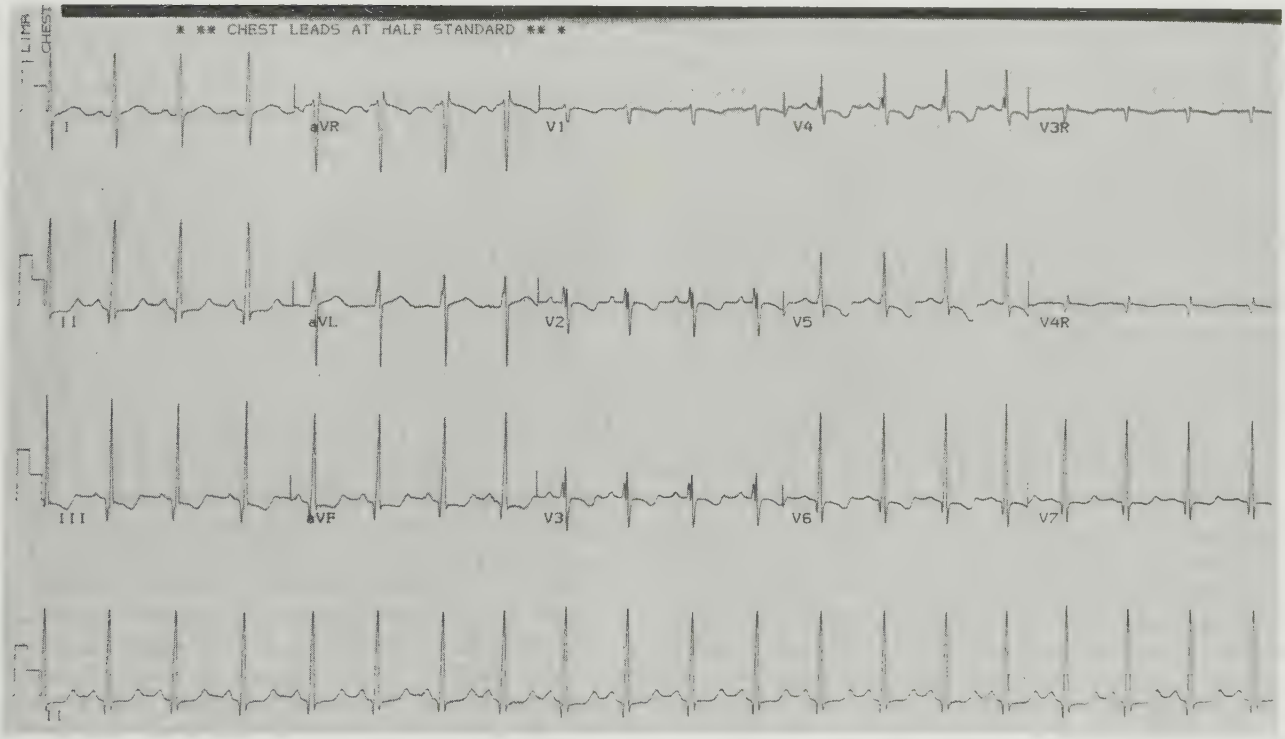

Fig. 80–15. Electrocardiogram (ECG) of a 9-month-old female with severe aortic coarctation. The tracing was interpreted to show left ventricular hypertrophy with left ventricular "strain" pattern. Note ½ std. chest leads. These ECG findings influenced decision for immediate surgery. Strain pattern was no longer present on postoperative tracing.

close the VSD in the same operation through a different incision; alternatively, the VSD may be closed several days later if the infant continues to require ventilator support. The 10 to 20% of infants in failure with coarctation who have isolated discrete obstruction will initially receive medical therapy and occasionally exhibit prompt and obvious improvement, in which case coarctation surgery is not performed. If poor feeding, poor weight gain, and respiratory difficulties are not reversed promptly, operation is offered. Coarctation repair is not offered electively to asymptomatic infants based on recognition of surgical risk and morbidity as well as knowledge that restenosis following repair in infancy is likely.

Unusual Coarctation

Less commonly identified forms of coarctation must be considered when a clinical diagnosis of coarctation of the aorta is made.[43] The usual isthmic narrowing just beyond the origin of the left subclavian artery can be accompanied by variations in related vessels such as patency of the ductus arteriosus, stenosis of the origin of the left subclavian artery, or anomalous origin of either left or right subclavian artery. In addition, coarctation can be found in an atypical location in the ascending aorta, transverse arch, distal thoracic aorta, or abdominal aorta. Extremely rare cases include the coexistence of multiple sites of coarctation and coarctation with right aortic arch and right descending aorta. Definitive diagnosis of one of these variations in anatomy depends on cardiac catheterization and angiography. Coarctation of the aorta proximal to the origin of both subclavian arteries invalidates the utility of arm and leg pulse differential in making the diagnosis of coarctation of the aorta.

Abdominal coarctation should be recognized in advance of surgery, so that the proper operative approach can be made. In contrast to the more common occurrence of thoracic coarctation in males, the abdominal site is more common in females. Clues to the presence of this alternate site of narrowing may be the presence of a murmur over the abdomen anteriorly and posteriorly as well as less obvious rib-notching which, when present, may be seen only at the borders of the lower rib owing to the limited possibility of development of collateral vessels in the abdomen. Historically, a patient may volunteer an important history of leg cramps with claudication. Abdominal coarctations are frequently longer in length and may involve the origin of the renal arteries or other abdominal aortic branches. Extreme cases of abdominal coarctation extend to and involve the origin of the femoral arteries (Fig. 80–14). Some authors have stated that abdominal coarctation is "always" acquired as part of an arteritis[44,45] which, when it affects the aortic arch and major vessels, has been referred to as "Takayasu's syndrome" or "pulseless disease."[46]

Histologically, Takayasu's arteritis is characterized by aortic segments that are narrowed by marked intimal hyperplasia and alternate with areas of aneurysm formation. The diffuse nature of the aortic involvement and the frequent association with a systemic illness similar to collagen vascular disease further typify this disease entity. The bizarre reversal of pulse discrepancy with obliterated upper extremity pulses and palpable femoral pulses and lower extremity hypertension, particularly when renal arteries are involved and femoral arteries are spared, is a curious presentation referred to by some as *reversed coarctation*. Whether isolated abdominal coarctation is ever a congenital anomaly or only exists as a post-inflammatory narrowing of the aortic lumen is not clear. But the progressive nature of this entity and its striking preponderance in females provides clinical overlap with recognizable Takayasu's disease.

Another condition, referred to as *pseudocoarctation*, is due to abnormal elongation and tortuosity of the aorta that does not result in sufficient narrowing of the lumen to allow measurement of an important gradient across the site of the kinking in the vessel.[47] This is further characterized by the lack of development of collateral vessels. Qualitatively, the medial ridge characteristic of true coarctation is present but its effect is slight. In a strict sense, pseudocoarctation and "kinking or buckling of the aorta" are probably forms of very mild coarctation. Occasionally, the appearance of pseudocoarctation may also be accompanied by a severe discrete coarctation. In these cases, a gradient at the site can be measured.

Multiple coarctation sites are rare. It is unfortunate when they are identified after repair of the coarctation in the usual site has not yielded relief of the gradient. Of interest is the recent recognition of the unusual occurrence of multiple coarctations (transverse arch as well as isthmic narrowings) in two Saudi infants, one with right aortic arch.

Functional coarctation may be produced by extrinsic pressure on the aorta by mediastinal masses or tumors. A dissecting thoracic aneurysm with involvement of the origin of the left subclavian artery may produce pulse discrepancy between the right and left arms. The rare spontaneous thrombosis of the aorta in the neonate may present like coarctation, resulting in a surgical emergency.[48] Disappearance of femoral pulses in the newborn may also be a complication of indwelling umbilical artery lines leading to thrombosis or vessel spasm.

NATURAL HISTORY AND COMPLICATIONS

The longterm prognosis of patients with unoperated coarctation of the aorta is primarily gleaned from autopsy studies rather than from longterm followup of patients with a clinical diagnosis of coarctation of the aorta.[13,60] According to these early reports, coarctation of the aorta was accompanied by a 90% mortality by age 50. The mean age of death was 35 years. Contributing to the cause of death were intracranial hemorrhage (11% of cases in autopsy series), aortic rupture or dissection (23%), endocarditis (22%), and congestive heart failure (18%).

The increased incidence of berry aneurysms in patients with aortic coarctation and the feared consequence of intracranial hemorrhage have been used to further support decisions for repair of aortic coarctation. Aneurysms of the circle of Willis (berry aneurysms) are thought to occur in up to 10% of patients with coarctation of the aorta. The likelihood of rupture appears to be greater in later years.[7] A review of cases of coarctation with death from cerebral aneurysm included its occurrence in the youngest case, a 13-year-old[62]; the average age at the time of death from intracranial hemorrhage was 28 years.[63] The observations that aneurysms were multiple in 4 of 11 patients and that the largest aneurysms were seen in older patients emphasizes the impression that longstanding hypertension promotes aneurysm growth.

There is evidence that the risk of intracranial hemorrhage correlates with the actual level of blood pressure; however, hypertension is not considered to be the sole causative factor. A congenital maldevelopment of the vessel wall predisposing to

aneurysm formation has been implicated. Mycotic aneurysms forming in the central nervous system, which in turn serve as the site for intracranial hemorrhage, are thought to be less common than the rupture of a congenital berry aneurysm. Following intracranial hemorrhage the likelihood of death is high, as is the risk of residual hemiplegia; however, there is also the potential for significant improvement in neurologic status, or even recovery.[63]

Cerebral aneurysm is usually silent until its rupture produces symptoms. When a ruptured aneurysm is found in a patient with aortic coarctation it is generally agreed that surgical treatment of both lesions will be necessary to try to alter the >75% probability of mortality. The timing and sequence of repair has been debated. Some authors favor initial treatment of the aneurysm, while others advocate that coarctation repair should take priority.[64]

Cerebral hemorrhage in neonates with coarctation of the aorta is extremely rare.[65] The late recognition of aortic coarctation in severely ill infants with previous cerebral hemorrhage may or may not be coincidental, as severe hypertension has not been documented prior to the hemorrhage. The management of an infant with coarctation and preexisting cerebral hemorrhage from whatever cause will complicate the decision regarding surgical therapy. It will be necessary to address whether emergency coarctation surgery is indicated or whether judicious repair of a mild or moderate coarctation will add additional risk and complicate recovery from antecedent (and possibly unrelated) cerebral injury.

Aortic rupture or dissection, as part of the natural history of coarctation of the aorta, is described as a cause of death in all large longterm natural history surveys of patients with coarctation of the aorta. In this lesion, rupture occurs in the thoracic aorta related to an intrinsic abnormality of the media complicated by hypertension compounding the usual stresses placed on the aortic wall. Aortic rupture in association with coarctation occurs at one of two sites. Approximately three fourths of the cases occur in the ascending aorta. Less often, aortic rupture occurs distal to the coarctation. The proximal rupture is more common in an older age group, after the third decade of life, and is associated with the same factors that predispose to dissecting aneurysms such as intimal "wear and tear," medial degenerative changes, or (less common) infection. Normal stresses imposed on the aortic wall are aggravated by elevated systolic blood pressure, explaining why aortic rupture is seen more often in the hypertensive patient with coarctation of the aorta. In a large series of patients under age 40 with dissecting aneurysms, approximately one third had coarctation of the aorta. With ascending aortic aneurysm death usually occurs from sudden hemopericardium caused by rupture of the aneurysm into the pericardial sac.

The obstetrical experience in unoperated coarctation of the aorta has found that aortic dissection or rupture during pregnancy is rare but is the main hazard of pregnancy in patients with coarctation. In these patients the rupture is generally found in the ascending aorta. Rupture occurs in the last trimester, during labor, or in the postpartum period. It is not agreed whether hormonal factors during pregnancy alter the biochemical composition or intrinsic structure of the aortic wall and thus predispose it to rupture[66] or whether a pre-existing medical necrosis of the wall is subjected to normal hemodynamic alterations of pregnancy, including hypertension, hypervolemia, and widened pulse pressure.[67] It is apparent, however, that there is a true increase in the incidence of dissecting aneurysm from coarctation during pregnancy.[68,69] It is not known whether early operative repair of coarctation of the aorta will protect against the development of irreversible structural changes in the aortic wall that in turn may predispose to rare aortic rupture during pregnancy.

Rupture of the distal aorta can also occur spontaneously and, unlike the more common proximal rupture, is seen more frequently in younger patients. Its occurrence is promoted by endocarditis at the site of the traumatic jet lesion that occurs on the wall of the aorta just beyond the coarctation. In fact, the role of infective arteritis as a causative mechanism is likely. The distal aortic site is also the location for traction aneurysms at the site of the ligamentum arteriosum, and the location for marked aneurysmal formation as part of post-stenotic dilation beyond the coarctation site. The hydrodynamic forces resulting from the jetting of blood through the coarctation site at high velocity have been implicated. With distal rupture, the aorta erodes into the left bronchus, esophagus, or left pleural cavity with rupture almost invariably sudden, dramatic, and fatal.

Endocarditis occurring with coarctation of the aorta is a cause of death that has been reduced through the years due to early recognition of the problem and improved antibiotic therapy.[63] The present projected incidence of 1.3% per year may in part be related to the additional liability of a bicuspid aortic valve. The infection is most likely to occur in the aorta just distal to the coarctation or on the bicuspid aortic valve. Confirmation of the site of infection is not always possible although improved recognition of vegetations with echocardiography may help. When aortic regurgitation becomes apparent during endocarditis, the aortic valve site is suspected. Endocarditis prophylaxis is recommended for use in all patients with coarctation of the aorta preoperatively as well as after surgical repair.

Congestive heart failure with coarctation of the aorta should raise the question of associated defects in infants as well as in those patients beyond the third or fourth decade of life when superimposed valvular heart disease, coronary artery disease, and renal disease become more likely. It does appear that the incidence of congestive heart failure increases with time and that left ventricular failure from longstanding hypertension is more evident after age 40.

The natural history of uncomplicated coarctation suggests that most patients can do quite well until early adulthood, when the risk of complications in association with unoperated coarctation begins to increase. In spite of the knowledge that systemic hypertension is a risk factor of coronary artery disease, myocardial infarction is not a major cause of death in patients with unoperated coarctation.[70] Theoretically, it is possible that adequate coronary flow is maintained by collateral circulation or an increase in the area of the coronary lumen. The morbidity and mortality from unoperated coarctation is high, prompting concern about interruption of the natural history of coarctation. Improvements in surgical therapy coupled with knowledge that prolonged preoperative hypertension and surgery after age 25 are associated with a risk of premature cardiovascular death have influenced pediatric cardiologists to consider that the optimal time for therapy of coarctation of the aorta is between ages 5 and 7.

THERAPY

The goal of therapy for all cases of coarctation is to offer a single definitive procedure at the time of lowest procedural risk

that in turn best affords long-term relief of hypertension. Medical management is justified when treatment of the patient will improve the risks and eventual outcome of surgery. Correction of coarctation of the aorta results only when relief of the mechanical obstruction is accomplished. Traditionally, this has been achieved by surgical therapy, although newer methods of dilation of the coarctation site by interventional catheterization are now available.

Medical Therapy

Medical treatment of patients with coarctation of the aorta is particularly applicable to the sick neonate presenting with severe congestive heart failure or shock. Prostaglandin infusion allows dilation of the ductus arteriosus and permits flow via the ductus beyond the coarctation.[71] Renal blood flow is enhanced, with reversal of hypoperfusion and shock; the goal is to make the infant a better candidate for surgery. Congestive heart failure is further improved by furosemide, with digoxin therapy added if ventricular function is assessed to be poor. Infants who have complicated coarctation are unlikely to respond to medical therapy alone, and the goal of treatment becomes that of stabilizing the patient in preparation for surgery. This management is based on a number of reports from several centers supporting a higher rate of survival with surgical treatment compared with medical treatment. There are staunch proponents of continued medical therapy alone for infants with isolated coarctation of the aorta based on the experience that a number of these infants will improve with time as collateral vessels develop over months of observation. With some of these children, medical therapy can be discontinued in late infancy or early childhood, allowing further growth of the child and surgical repair of the coarctation electively performed at school age. Others would recommend repair of isolated coarctation at any age if the patient is symptomatic.

Enthusiasm for medical treatment of coarctation hypertension with beta-adrenergic blockers or other antihypertensive agents is difficult to support if one believes that the upper body hypertension is a normal compensatory mechanism brought into play to overcome the resistance imposed by the obstructing coarctation. If the blood pressure elevation is so severe that it requires treatment by pharmacologic means, it seems likely that surgery should be performed.

Abdominal coarctation of the aorta may present special problems in that more severe hypertension is seen in this condition, particularly when there is associated renal artery involvement. Treatment of hypertension by medical means alone is usually impossible and can be dangerous, and an attempt at surgery is generally preferred. Treatment of residual hypertension, once surgery has been performed, may be a longterm compromise if no further surgical procedure would be beneficial.

Surgical Therapy

The earliest method of repair of coarctation in an experimental animal was reported by Blalock and Park in 1944, with acute experiments using the left subclavian or left carotid artery to bypass the created coarctation segment in an end-to-side manner.[72] A high incidence of postoperative paralysis was reported as a result of interference with arterial supply to the spinal cord.

Surgical correction of coarctation of the aorta in humans was first performed in October, 1944, by Drs. Crafoord and Nylin in Sweden[73] and in July, 1945, by Drs. Gross and Huffnagel in Boston.[74] These physicians demonstrated that in the presence of well-developed collaterals, the aorta could be safely cross-clamped just above and below the coarctation site, allowing removal of the coarcted area followed by re-approximation of the ends of the aorta. This operation, using resection and end-to-end anastomosis, remains the standard surgical form of therapy today in individuals with localized discrete obstruction. Overall operative mortality is highest (16.4%) in patients under 1 year of age, falling to 1.4% in patients 1 to 69 years of age.[75] The surgical approach is by way of a left posterolateral thoracotomy through the fourth left intercostal space using a curved incision extending from the anterior axillary line to the tip of the scapula. In children the ribs are spread to allow surgical access, whereas rib resection may be necessary in adults. If additional intracardiac repairs are necessary, the excision is extended across the sternum, with transection of the sternum, and both fourth intercostal spaces are entered. The patient is not usually placed on bypass since well-developed collaterals permit safe cross-clamping of the aorta. A ductus or ligamentum is usually divided to enhance mobility of the aorta. The best result, with the lowest chance of recoarctation, is thought to be gained when a continuous suture line is used posteriorly and completion anteriorly is done with interrupted absorbable vascular sutures to allow for growth of the anastomosis (Fig. 80–16).[76]

When the anatomy of the coarctation segment varies, alternative repair methods may be required (Fig. 80–17). Proponents of patch graft aortoplasty,[77] as first proposed by Vosschulte in 1957, believe it may be simpler to incise the area of coarctation longitudinally, resect the coarctation shelf, and insert an elliptical Dacron patch across the area allowing extension of the patch up onto the base of the left subclavian artery. Other techniques using interposition grafts and conduits placed in parallel to the descending aorta have been used in special circumstances, with stated advantages being that there is less mobilization of the aorta required, fewer injuries to the recurrent laryngeal nerve, and avoidance of a circular constricting anastomosis.

Due to a high rate of restenosis—up to 60% when resection and end-to-end anastomosis was used in infants[78]—Waldhausen and Nahrwold devised a repair using a flap of the subclavian artery.[79] In this operation the subclavian artery is ligated distally and a vascular pedicle is created from the subclavian, which is then used to bridge the hypoplastic segment. The vertebral artery must always be ligated to avoid subclavian steal.[80] Resultant mild discrepancy in limb length occurs after ligation of the subclavian, similar to that recognized after Blalock-Taussig shunts.[81]

Proponents of this method of repair are enthusiastic that the vascular subclavian flap as well as the posterior wall of the aorta will grow, and that the avoidance of a circumferential suture line is ideal.[58,82] Other surgeons report that restenosis with this method of repair is high (and perhaps "inevitable" when an infant under 8 weeks of age has subclavian flap repair because of involution of ductal tissue and perhaps the further growth of the coarctation shelf that is left behind).[83] The previous claims that the incidence of restenosis would be much lower than with resection and end-to-end techniques may not be true.[84,85] The subclavian flap procedure (Fig. 80–18) may be preferable in infants in whom the resection and end-to-end procedure will leave an unacceptably small anastomosis due to additional severe isthmic hypoplasia. No one method of repair is ideal for all patients. The best repair in a child would seem to circumvent the need for prosthetic materials

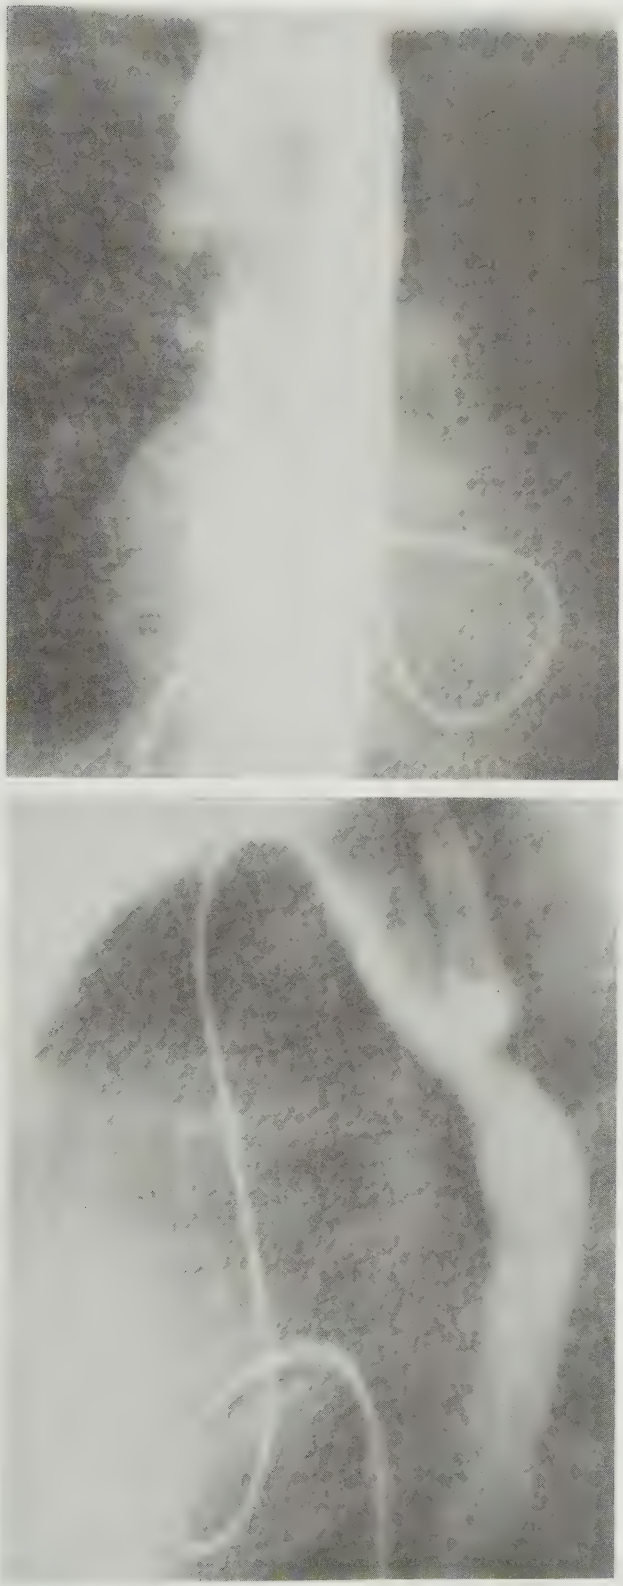

Fig. 80–16. Aortogram performed 23 years after repair of coarctation of the aorta by resection and end-to-end anastomosis in a 15-day-old female. The pressure measured proximal to the repair was 125/80 mm Hg, and 130/75 mm Hg distal to the repair on withdrawal tracing at catheterization.

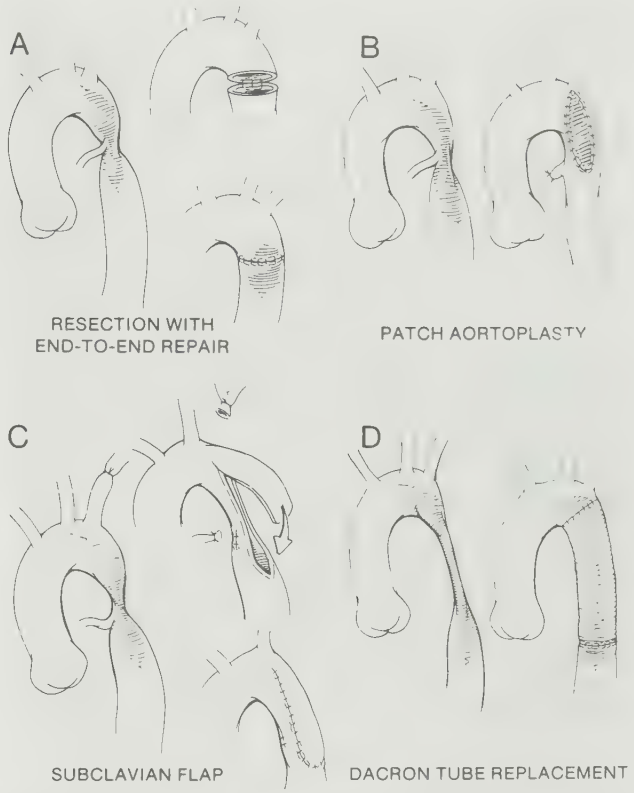

Fig. 80–17. A–D. Methods of surgical repair of aortic coarctation (see text).

and allow for growth of the surgical area. Residual gradients and need for reoperation are most often found when surgery is necessitated at a young age; the age seemingly has greater influence than the technique used.

Information on the normal growth of the aorta projects that the aortic diameter increases threefold from birth to maturity, with the most rapid change occurring in early childhood.[86] The diameter of the aorta at 3 years of age is 55% the diameter in adulthood. Physiologic evidence agrees with experimental data indicating that important obstruction to blood flow through a stenotic orifice occurs when the diameter is reduced by 50% or greater. Optimally, the earliest time that successful operation is expected is age 3 years, with provisions that the surgeon entirely excise the area of constriction and complete the end-to-end anastomosis without compromising lumen size by the circumferential anastomosis. At this age, even if the anastomosis did not grow, it would not result in more than a 50% stenosis and would not produce a gradient.

When surgery is offered, surgical judgment and experience in choosing a technique based on the anatomy encountered will offer the best relief of obstruction and least likelihood of recoarctation. The potential for restenosis exists unless the coarctation shelf lesion is completely removed as well as the encircling "ductal tissue," if present.

Intraoperative and Postoperative Complications

Important complications related to coarctation surgery are infrequent but include 1) recurrent laryngeal nerve injury; 2) phrenic nerve injury; 3) predisposition to bleeding both from collateral

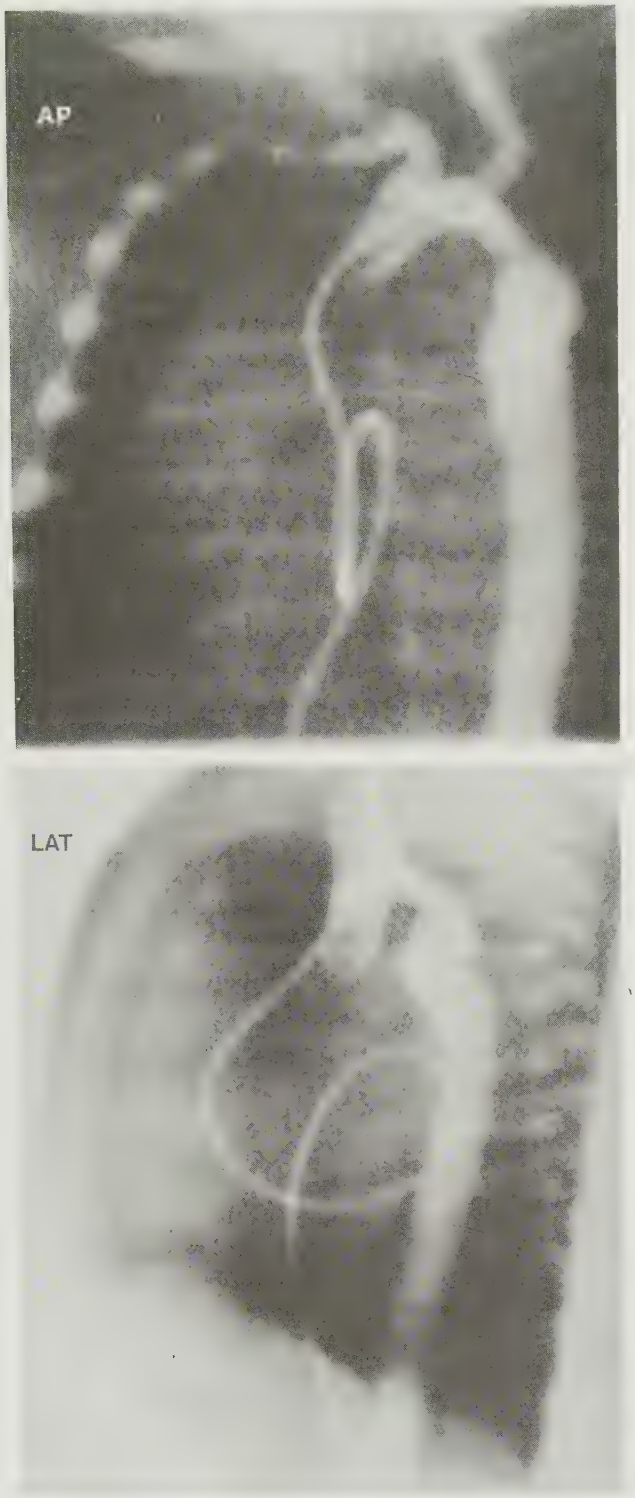

Fig. 80–18. Repair of aortic coarctation at age 4 days by subclavian flap technique. Aortic root angiogram performed 2 weeks postoperatively reveals patency of the repair with persistent hypoplasia of transverse arch. Infant has Taussig-Bing anomaly in addition to coarctation. Withdrawal pressures: ascending aorta 84/42 mm Hg, transverse arch 76/42 mm Hg, descending aorta 72/42 mm Hg.

vessels and from the high pressure aortic suture line; 4) chylothorax; 5) postcoarctectomy syndrome (mesenteric arteritis); 6) paradoxical postoperative hypertension; and 7) spinal cord ischemia.

Traction or electrocautery can injure the recurrent laryngeal nerve as it loops around the ductus or ligamentum before its ascent; this problem is manifest clinically as persistent hoarseness. Even less frequently, the phrenic nerve, located more anteriorly on the border of the pericardium, can be injured and result in unilateral diaphragmatic paralysis.

Bleeding from extensive chest wall collaterals or from the high pressure suture lines on the aorta is the most common postoperative problem following coarctation repair. Bleeding is lessened if preclotted synthetic materials are used for prosthetic reconstruction. Catastrophic disruption of the suture line with resultant hemorrhage has occurred early after subclavian flap repair and late, on another occasion, when postoperative endocarditis weakened the area of surgical repair.

Chylothorax may result from tearing or perforation of the thoracic duct, which, because it crosses behind the aortic arch and left subclavian artery,[87] is vulnerable during dissection. Nonoperative management of this complication with multiple thoracenteses, chest tube placement, and a diet of medium chain triglycerides is often effective; however, surgical treatment of this complication before caloric and protein losses are severe should be considered when chylous drainage persists. The fairly constant entry of the thoracic duct as it enters the thorax through the aortic hiatus in the diaphragm allows ligation, although reportedly 28% of individuals may have two or more major ducts at the level of the diaphragm.[88] The management of postoperative chylothorax is discussed in detail in Chapter 151.

A postoperative problem unique to coarctation repair is that of postcoarctectomy syndrome (mesenteric arteritis).[89,90] When forceful pulsatile flow is introduced postoperatively to vessels beyond the coarctation, thin walled arterioles overdistend and may rupture. Mesenteric vessels, poorly supported by surrounding tissue, are particularly at risk for damage. In addition, reflex arteriolar vasoconstriction occurs in distal vascular beds, contributing to postoperative hypertension. Clinical manifestations are abdominal pain, abdominal distention, vomiting, and decreased bowel sounds with progression to an "acute abdomen" when hemorrhage into the intestinal wall occurs. In severe cases, laparotomy may be required for treatment of bowel necrosis. This complication is thought to be more common if feedings are introduced early postoperatively. To avoid the development of this problem, nasogastric tubes are left in place for 48 hours postoperatively and the patient is continued NPO for at least 72 hours. Feeding is begun slowly with clear liquids with rapid progress to a full diet. Important systolic hypertension is treated as well as diastolic pressures in excess of 95 to 100 mm Hg, since hypertension appears to be an essential component of the syndrome.

The mechanism of postoperative rebound hypertension seen after successful repair of coarctation is partially explained on the basis of reflex vasospasm in the vascular beds distal to the coarctation[91,92] as well as a baroreceptor-mediated role for increased sympathetic activity. It is not unusual for blood pressure to return to or exceed preoperative levels and require treatment. Control of postoperative rebound hypertension may be important in decreasing the frequency of postcoarctectomy syndrome.[93]

The most feared consequence of surgery is paralysis of the lower extremities resulting from spinal cord injury. Fortunately, this is rarely reported. The incidence is less than 0.5% in more than 12,000 cases compiled in experience from several cardiovascular centers.[94] No one specific factor is implicated as causative in all cases where paralysis has resulted after surgery; however, the risk may be increased by prolonged aortic cross-clamping, reduced arterial collateral vessels, sacrifice of intercostal vessels during repair, or even hyperthermia.[95] A clue to the possible development of a serious problem is that when the aorta is cross-clamped, the proximal blood pressure rises dramatically and the distal aorta is observed to become nonpulsatile and collapsed. This is explained on the basis of poor development of a well-developed and protective collateral supply. It is possible that immediate recognition of this problem would allow removal of surgical clamps with reversibility of the brief neuronal ischemia resulting from circulatory failure. If collaterals are judged preoperatively to be inadequate, the need for surgery should be carefully reassessed. If surgery is required, further methods of cord protection could be employed, including hypothermia, cardiopulmonary bypass, or bypass graft repair with only partial aortic clamping. There is no definite rule about the number or location of intercostal vessels that can be safely sacrificed during coarctation repair. The best protection against neurologic sequelae from operation is thought to be the presence of a well-developed collateral circulation.

Surgical therapy remains the most definitive means of effecting relief of obstruction. Because of its role in managing coarctation of the aorta successfully for over 40 years, surgical intervention is the standard against which new treatments must be compared.

Therapy with Interventional Catheterization

Coarctation of the aorta can be successfully dilated with balloon angioplastic techniques (Fig. 80–19). The feasibility of relieving obstruction, particularly when discrete, has been reported from many centers.[96,97] This method of treatment is still controversial and requires comparison with surgical treatment. It is still not known whether recurrence rates for coarctation will be higher with dilation procedures or if other longterm complications will be a problem.

Originally, percutaneous transluminal angioplastic techniques were demonstrated to be effective in patients who had developed restenosis after previous coarctation surgery.[98] Recurrent coarctations appearing after surgical end-to-end anastomosis, patch angioplasty, and subclavian flap have been successfully dilated. It has been hypothesized that there is protection against rupture of the aorta resulting from postoperative scarring and fibrosis of the aortic wall. It is thought that, in spite of the higher inflation pressures required for dilation of restenosis lesions, vessel integrity will not be compromised. For successful angioplasty, the intima and part or all of the media is disrupted when the vessel diameter increases.[99] Although late healing may be complete, the potential for aneurysm formation immediately or in longterm followup has raised concern about this procedure. Unusually high rates of aneurysm formation reported by some centers may be further substantiated by others who are carefully following postangioplasty patients.[100] Aneurysm formation does not invariably occur, however, and its occurrence is rare on short-term prospective followup in our institution.[42] Furthermore, aneurysm after coarctation repair is also found in surgical series, as discussed later in this chapter.

The procedure is described in detail in Chapter 130. Briefly, the technique involves the retrograde insertion of a dilating catheter over a guide wire from a femoral or umbilical arterial approach. Concern for overdistention and rupture of the aorta have resulted in conservative calculations for the effective dilation diameter of the balloon. Inflated diameters should be 2½ times that of the diameter of the coarctation, or, the balloon should be 1 to 2 mm greater than the diameter of the aorta measured at the base of the left subclavian artery. The catheter is positioned in the aorta with the midpoint of the balloon at the narrowest site and the balloon is inflated with dilute radiopaque contrast medium for a few seconds to achieve elimination of the waste produced by the coarctation lesion. The actual dilation of the coarctation is painful and patients should receive appropriate preprocedural sedation. Effective reduction in pressure gradient across the coarctation site is immediately apparent, as is angiographic evidence of widening. In certain circumstances, the use of two angioplasty balloons is preferable.

As with other interventional techniques, the significant advantages of a shorter hospital stay (average of three compared with 10 days), cost containment, and psychologic and cosmetic avoidance of operation must be considered. Postprocedural problems with paradoxical hypertension and/or postcoarctectomy syndrome are reportedly rare.[42,101] These considerations are less important if benefits of angioplasty are incomplete and further surgery is required. If treatment of coarctation of the aorta by dilation procedures results in weakening of the aortic wall with aneurysm formation and an increased longterm potential for rupture, traumatic injury to the aorta that promotes accelerated atheroma formation, or other unrecognized problems, then surgical treatment will continue to be a better longterm answer for these patients. The risk of injury to the femoral arteries also needs to be addressed. A particular concern has been raised relevant to the case with successful relief of coarctation gradient and an aneurysm resulting from the procedure that requires resection. In this setting, collateral vessels might have regressed, eliminating their protective effect during aortic cross-clamping; thus an operative technique may have to be used that includes methods for perfusing the lower body.

In spite of unanswered concern about the longterm effectiveness and margin of safety of treatment with coarctation dilation, there are circumstances wherein this treatment may be offered or preferred. If thoracotomy is considered especially high risk because of previous surgery, bleeding diathesis, associated medical conditions (for example, ruptured cerebral aneurysm), or perhaps in patients who place restrictions on the use of blood products, dilation may be a safer technique. The use of dilation procedures in infants is not clearly established, but when performed early, the approach can be from the umbilical route, sparing trauma to femoral vessels.[54,55] It is possible that this technique will offer enough palliation of infants who have severe left ventricular dysfunction in association with coarctation to allow postponement of surgery. Concerns from autopsy studies of patients with large areas of ductal tissue in the area of constriction project that balloon angioplasty will palliate only temporarily and that restenosis is inevitable.[102]

The availability of dilation techniques will prompt further followup of all patients with coarctation to compare treatment options. At this point the challenge to proponents of dilation pro-

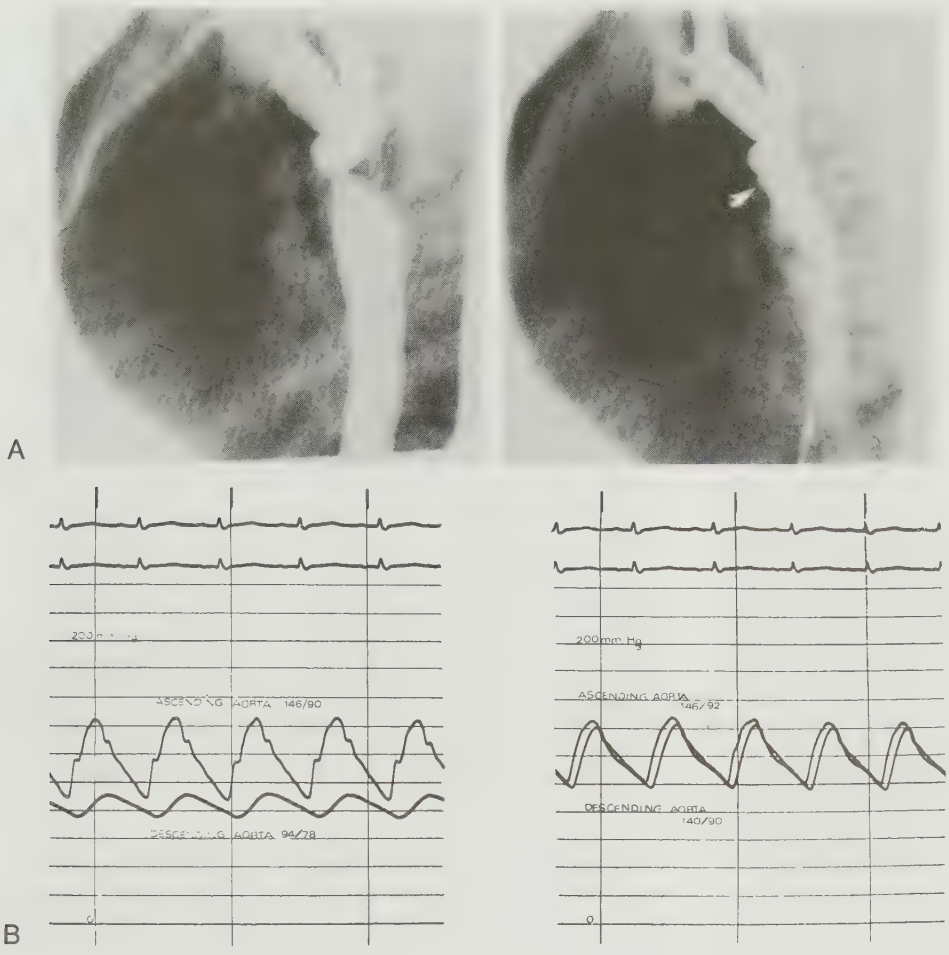

Fig. 80–19. Coarctation of aorta in a 5-year-old boy. A. Lateral angiogram prior to balloon angioplasty of aortic coarctation (left) and immediately following balloon angioplasty (right). Significant widening of the coarctation area has resulted, with minimal disruption of intima (arrow). B. Pressure tracings simultaneously recorded from ascending aorta and descending aorta prior to balloon dilation (left) and following dilation (right). The preprocedural peak gradient (52 mm Hg) was reduced to 6 mm Hg after dilation.

cedures for coarctation of the aorta is less proof of feasibility than longterm efficacy and safety of the technique.[103]

Postoperative Followup and Outcome

Natural history studies of coarctation confirm the high risk of mortality in infants as well as the shortened life expectancy for adults with isolated coarctation. With the availability of surgery, coarctation is now considered to be a defect that can and should be treated by operation. The likelihood of surgical success is dependent foremost on the age and size of the patient when operation is performed although the anatomy and technique of repair may also influence the outcome. Most pediatric cardiologists recommend elective correction of coarctation for all patients beyond the age of 3 years but before 10, despite lack of symptoms or severe upper extremity hypertension. Infants with a ventricular septal defect and coarctation who required pulmonary artery banding at the time of initial coarctation repair may have pulmonary debanding and ventricular septal defect closure in childhood with reoperation for coarctation postponed until adolescence. When surgery is offered beyond age 1 year, repair should consist of resection and end-to-end anastomosis unless unfavorable anatomy dictates an alternate method of repair. The application of subclavian flap techniques in young infants is enthusiastically supported at this time, although the claims of significantly lower incidence of restenosis have not been as fully evaluated as the resection and end-to-end technique. Long-term results of resection versus patch aortoplasty repair for coarctation are comparable in some centers.[104] In evaluating the longterm results, the distinction needs to be made between poor relief of obstruction and recoarctation or lack of growth of the anastomotic site.[105]

Long-term followup of all patients with coarctation of the aorta is mandatory. Aortic aneurysms are a long-term sequela of repairs using patch graft and tubular graft technique.[106] The aneurysms are thought to result because of the change in tensile strength rendered to the circumference of the vessel.[107,108] When these techniques are used, selection of patch material may play a role. In general, a patch graft aneurysm is found on the aortic wall opposite the patch graft. This situation occurs because the patch is less elastic than the aortic wall and the pulse wave is transmitted to the aorta opposite the graft. False aneurysms have formed at suture lines following partial disruption, with infection having a contributory role in some instances. Structural weakness in the arterial wall due to atherosclerosis may also be important in causation. The differences in reported frequency of postoperative aneurysms vary with the length of followup and awareness of the problem. The incidence estimated by one group using patch angioplasty repair is as high as 38% by 14 years postoperatively.[109] Often, followup roentgenographic studies will provide a clue to aneurysm formation. A rare presentation with development of hoarseness from compression of the recurrent laryngeal nerve has also been found. Aneurysm formation after patch angioplasty in children is recognized, thus, advanced age is not a necessary factor.[110]

Some surgeons, because of the concern about vessel rupture, aggressively approach aneurysms developing after dilation tech-

niques. In other institutions, these aneurysms are observed without reoperation, based on the conjecture that the aortic wall may heal enough to make rupture unlikely. Operation for removal of an aneurysm is hazardous since the previous complete or excellent relief of the obstruction has encouraged regression of collateral flow. Cross-clamping of the aorta without perfusion techniques to protect the spinal cord might no longer be safe. Femoral–femoral bypass is often instituted in this situation.

Suggestions of improved survival and a lower incidence of subsequent coronary heart disease and cardiovascular events if surgery is performed at a younger age have prompted elective repair in childhood. This practice is further supported by findings that the period and degree of preoperative hypertension has some influence on whether hypertension will recur on followup or be poorly relieved by operation.[70,111] These considerations, as well as projections about normal growth of the aorta, have prompted pediatric cardiologists to recommend elective repair beyond 3 years of age but under 10 years of age.

Persistent hypertension after surgery is usually related to insufficient anastomosis width. This may be apparent soon postoperatively, with incomplete relief of obstruction, or much later, with "recoarctation" or failure of growth at the site of repair. Persistent hypertension independent of a residual pressure gradient may not, in fact, be greater in the population with operated coarctation when compared with the incidence of essential hypertension in the general population.[61,112] Adjunctive information obtained from exercise stress testing has been valuable in assessing some patients after coarctation repair.[113,114] Proponents of this testing feel that exercise augments any residual systolic gradient at the coarctation repair site and therefore is a more sensitive indicator of residual obstruction.

The belief that the incidence of calcific aortic stenosis as a late occurrence is low in patients with bicuspid aortic valve in association with coarctation has been emphasized by several authors.[112,115,116] It has been stated that initially insignificant aortic valve disease, without an aortic valve gradient at the time of coarctation repair, usually does not progress. Congenital aortic stenosis with coarctation is well recognized. On the other hand, late calcific changes in the bicuspid valve not documented to be stenotic at the time of coarctation repair are rare. A patient known to us had coarctation repair at age 13; no gradient was measured at the time of preoperative catheterization but bicuspid aortic valve was recognized. Severe calcific aortic stenosis with a 90 mm Hg gradient at catheterization necessitated valve replacement at age 29. The recent observations that an "equally bicuspid" aortic valve is the type seen more often in association with coarctation leads to the conjecture that a lower incidence of calcific change may be related to a less turbulent flow pattern.

The lifetime threat of endocarditis is addressed with continual use of antibiotic prophylaxis for dental and surgical manipulations. Insurability of patients with coarctation of the aorta is best in the group who have had a good result from operation. If postoperative patients are asymptomatic, are normotensive, and have gradients between arm and left cuff pressures of less than 10 mm Hg, they may obtain life insurance at standard rates from most large companies, although they may be required to pay more than standard rates.[117] Employment opportunities based on individual capabilities should not be dissimilar from those of peer groups. Assistance from cardiologists may be required in clarifying these concerns on an individual basis. Attention to residual coarctation may qualify patients for insurance when reoperation or dilation techniques are successfully performed.

Recommendations for the obstetrical management of the patient with coarctation of the aorta will vary; generalization is not possible.[118] In the patient who has had successful repair of coarctation, pregnancy may be anticipated to proceed without difficulty. Careful monitoring of blood pressure and use of antibiotic prophylaxis would seem prudent. It is possible that an individual patient may have aortitis or cystic medial necrosis complicating coarctation, which will persist even after successful repair,[119] so that pregnancy risks are still not completely defined. The recurrence risk of coarctation in offspring is low, in the range of 3%.

SUMMARY

Coarctation of the aorta is generally placed on the list of congenital cardiac defects that can be cured by surgery. Nevertheless, all patients require lifetime followup,[120,121] as one or more of the following problems may ultimately develop: 1) infective endocarditis, 2) calcific aortic stenosis, 3) aortic regurgitation, 4) mitral valve dysfunction, 5) systemic hypertension, 6) restenosis at coarctation site, 7) aneurysm of the aorta, either at the site of previous procedure or a "spontaneous dissection," 8) cerebrovascular accident, 9) complication of pregnancy, and 10) premature atherosclerotic cardiovascular disease.

A longer duration of preoperative hypertension has been observed to contribute to the risk of many of these complications. Optimistically, isolated coarctation when repaired successfully past the age of 3 years should allow for sufficient width of the anastomosis and permit normalization of blood pressure. It is hoped that the longterm followup of these younger patients will demonstrate that complications described in the unoperated natural history of coarctation can be eliminated by appropriately timed correction of the anomaly.

INTERRUPTION OF THE AORTIC ARCH

Interruption of the aortic arch is a congenital anomaly in which complete discontinuity exists between the ascending and the descending aorta in some location (Fig. 80–20).[122–125] When the aorta is represented by a cord of tissue without patency or when the lumen is completely obstructed without discontinuity of the vessel, the term *atretic segment* should be used. Interrupted aortic arch occurring as an isolated defect is rare. In interrupted aortic arch the descending aorta is almost always connected to the pulmonary artery by way of a patent ductus arteriosus. A VSD is usually present. In fact, the association of interrupted aortic arch, VSD, and ductus arteriosus is the usual situation. Interrupted aortic arch represents less than 1% of all congenital heart anomalies. The condition is usually fatal in infancy if untreated. Aggressive intervention has improved the potential for survival and possible favorable outcome.

ANATOMY

The site of interruption has important implications from a diagnostic as well as a surgical standpoint. The most familiar classification used is that of Celoria and Patton, based on the site of interruption with respect to the origin of the major branches from the aortic arch.[126] As schematically illustrated in Figure 80–21, type A interruption occurs distal to the left subclavian artery. Type

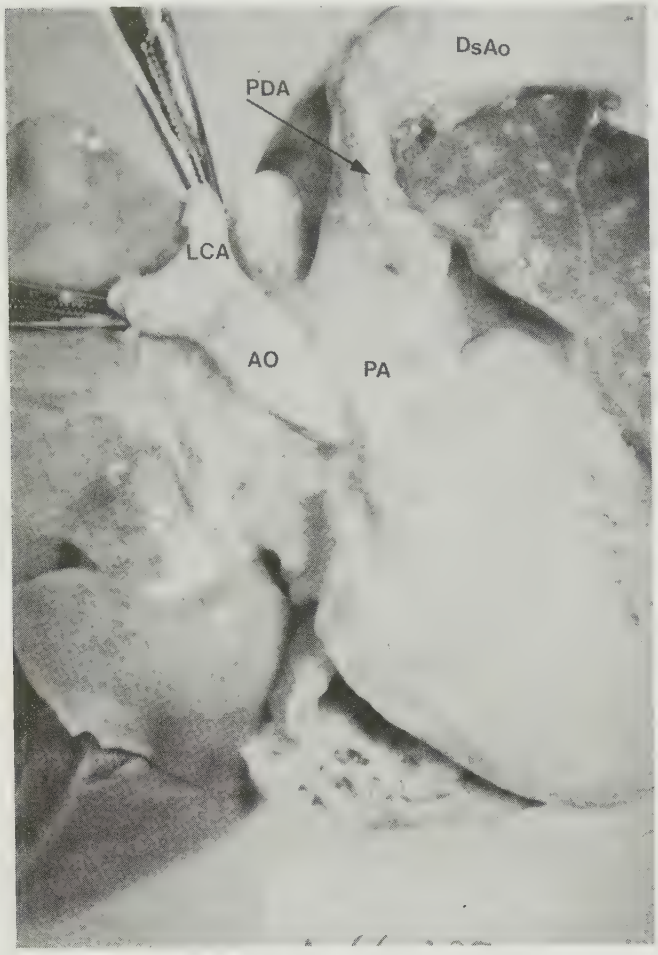

Fig. 80–20. Interrupted aortic arch, type B. Gross specimen. There is complete discontinuity in the aorta (AO) occurring just beyond the origin of the left carotid artery (LCA). The ductus (PDA) courses from the main pulmonary artery (PA) to supply the descending aorta (DsAo).

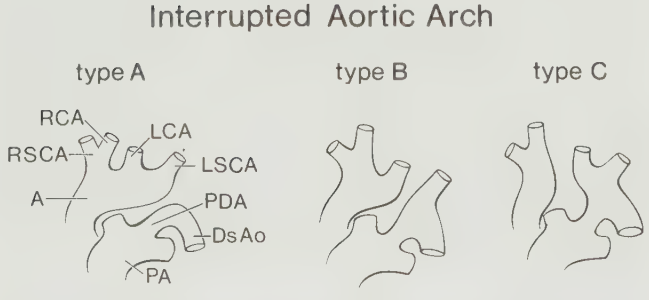

Fig. 80–21. Classification of interrupted aortic arch (with left aortic arch). Type A: Interruption distal to left subclavian artery (LSCA). Type B: Interruption between left carotid artery (LCA) and LSCA. Type C: Interruption between right innominate artery and LCA. A = aorta; RSCA = right subclavian artery; RCA = right carotid artery; PDA = patent ductus arteriosus; PA = pulmonary artery; DsAo = descending aorta: Right innominate branches RSCA and RCA are illustrated.

B refers to interruption between the left subclavian and the left carotid arteries. Type C interruption is present when there is a lack of continuity in the aorta between the right and left carotid arteries. Type B is the most commonly occurring form (approximately 53% of cases). Type A is present in 43% of cases, and type C in 4%. To our knowledge, interruption distal to the entry of the ductus has not been described. A VSD coexists in approximately 50% of patients with type A interruption and more than 80% of patients with type B interruption.[127] The high occurrence of an unusual type of VSD seen with type B interruption deserves emphasis.[128] The VSD is commonly a muscular outlet defect associated with malalignment of the trabecular and infundibular septum. Posterior deviation of the infundibular septum provides the substrate for subaortic obstruction, which may not be manifest until VSD closure has been accomplished (Fig. 80–22A).

Interrupted aortic arch is found with greater than expected frequency in conjunction with conotruncal abnormalities (including truncus arteriosus), and origin of both great vessels from the right ventricle with subpulmonary VSD (Taussig-Bing complex).[123,129] Less frequent associations are with aorticopulmonary window, single ventricle with transposition, and endocardial cushion defect with Down syndrome. Bicuspid aortic valve and narrowing of the subaortic outflow area as well as other potential left heart obstructive lesions, including mitral valve atresia or stenosis, should be sought in evaluation of a patient with aortic arch interruption. It is extremely rare for interrupted aortic arch to be present without a ductus arteriosus or other abnormality.

EMBRYOLOGY

The usual embryologic explanation for interruption of the aortic arch focuses on maldevelopment of the aortic arch system with early failure of formation or later regression of specific segments.[126,130] There are proponents of other, more basic, mechanisms based on altered intrauterine flow dynamics. These latter theories implicate patterns of decreased prograde aortic flow resulting in hypoplasia of the ascending aorta and regression or atrophy of "unused" aortic segments. A brief review of the development of the aortic arch system will make it conceptually easier to understand the embryologic events that might result in the repeated patterns of interruption (Fig. 80–23). With normal fetal development, blood flow to the head and upper extremities is separated at the level of the ductus from blood flow to the trunk and lower extremities. Type A interruption occurs when the discontinuity is in the segment of dorsal aorta between the fourth arch and the insertion of the ductal portion of the sixth arch. The migration of the left subclavian artery upward has occurred and its final position proximal to the site of interruption in type A interruption suggests an intrauterine event after the seventh week of gestation. With type A interruption, the head, neck, and upper extremities are supplied from the arch branches, with the distal aorta supplied from the pulmonary artery by way of right-to-left flow in the ductus arteriosus. With this site of involution distal to the subclavian artery and proximal to the ductus, the isthmus of the aorta is uniquely absent. Van Mierop and Kutsche have described how type A interruption and infantile coarctation are closely related, prenatally acquired lesions and contrast in several ways with type B interruption.[127]

Type B interruption occurs when there is involution or failure

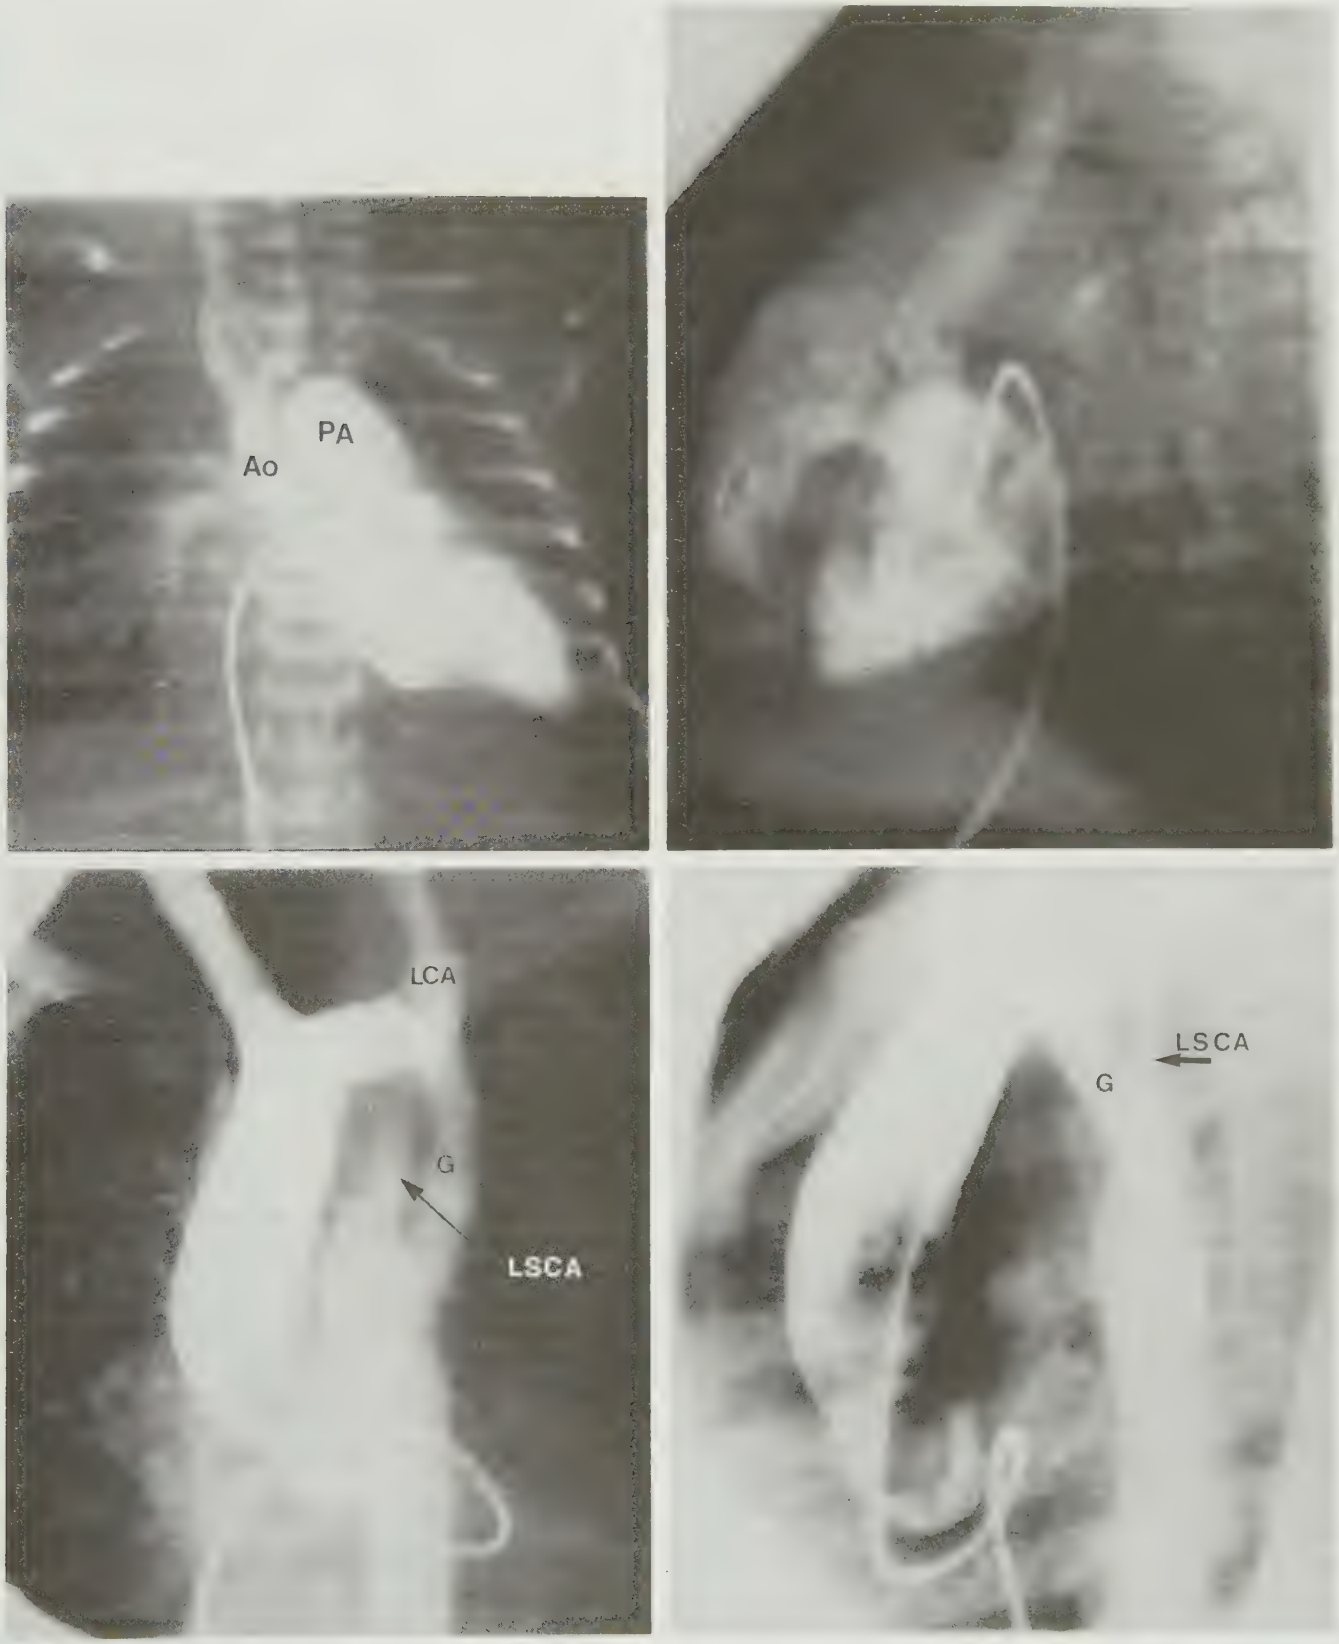

Fig. 80–22. (A) Interrupted aortic arch in a 3-day-old infant. AP (left) and LAT (right) angiogram-LV injection. Findings of markedly dilated pulmonary artery (PA) compared to small ascending aorta (Ao). The Ao appears to end just beyond the origin of the second branch, the left carotid artery (type B interruption). The ventricular septal defect (VSD) is outlined on the lateral frame with subaortic narrowing suggested due to deviation of infundibular septum (see text). (B) Interrupted aortic arch, type B. AP (left), LAT (right) angiographic frames. Six years after reconstruction with interposed 8 mm Gore-tex graft (G) placed between transverse aortic arch (at origin of left carotid artery [LCA]) and descending aorta. The left subclavian artery (LSCA) originally arose from the descending aorta beyond the interruption. Ascending aortic pressure is 100/60 mm Hg, femoral artery pressure 95/60 mm Hg.

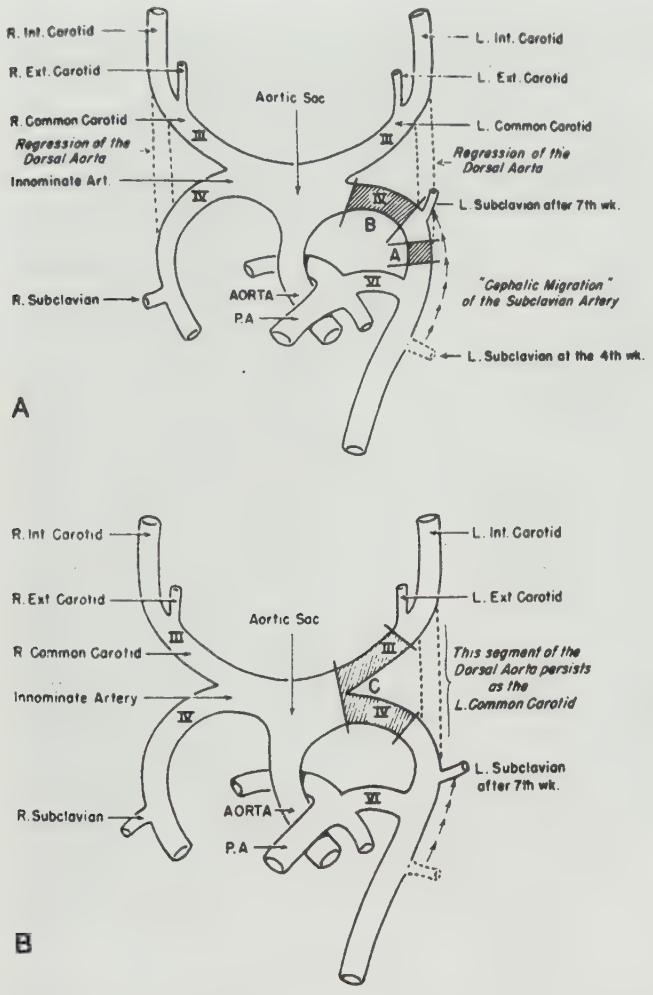

Fig. 80–23. (A) Schematic representation of primitive aortic arches from which great arteries are derived. Sites of aortic arch interruption, types A and B, are indicated. (B) Site of type C interruption. (Figure reproduced with permission from the American Heart Journal and Celoria, G.C., and Patton, R.B.: Congenital absence of the aortic arch. Am. Heart J., *58*:407, 1959.)

of formation of the left fourth arch as well as that segment of dorsal aorta between the fourth and sixth arches. Its occurrence must be prior to the seventh week of gestation, when the subclavian artery would have normally ascended. The subclavian artery arising below the interruption from the superior portion of the descending aorta, is supplied in the same manner as the lower body, by way of the ductal flow from the pulmonary artery.

The explanation for development of type C interruption distal to the innominate vessel is less clear (Fig. 80–23B). Two theories have been proposed. The first implicates complete failure of development of the left third and fourth arches, which would be replaced by persistence of the segment of dorsal aorta (earlier present between these arches) forming the left carotid artery. Seemingly more plausible is a second theory outlining failure of the left portion of the aortic sac to communicate with the third and fourth arches, allowing fusion of the left third and fourth arches to form the left carotid artery.

Proponents of the flow theory for intrauterine development of interrupted aortic arch outline the frequency with which the associated congenital defects serve to divert flow from the ascending aorta and increase flow by way of the pulmonary artery and ductus.[23] The unusual malalignment subpulmonary VSD and the leftward shift of the infundibular septum, producing narrowing of the left ventricular outflow tract above the level of the VSD, contribute to increased pulmonary flow at the expense of decreased aortic flow. This theory is further supported when transposition of the great arteries, VSD, and interrupted arch coexist as the role of rightward shift of the crista is recognized. Although the great majority of cases of interrupted aortic arch occur with intracardiac defects that cause reduced antegrade flow to the aorta, this does not explain every case. During fetal life, the circulatory burden imposed by interrupted aortic arch is slight since hemodynamics of right-to-left ductal shunting are the norm for all fetuses.

Even more embryologically complex is the association of interrupted aortic arch and third and fourth pharyngeal pouch defects, including absence of the thymus and parathyroid glands.[127] The term *DiGeorge syndrome* encompasses the immune defect resulting from thymic aplasia, with hypocalcemia as a result of parathyroid agenesis, and includes a striking frequency of type B interrupted arch, which occurs in at least 30% of cases. Conversely, 68% of patients with interrupted arch type B had DiGeorge's syndrome. Forms of aortic arch interruption other than type B exist with DiGeorge syndrome but are rare. The physical appearance of these children is distinct. An abnormal karyotype has been identified in some patients, characterized by partial monosomy of chromosome 22.[132,133] Immunologic abnormalities may be less severe in partial DiGeorge's syndrome, with hypoplasia rather than absence of thymic tissue, though here too a high association with aortic arch anomalies is present.[134] It is prudent to recommend investigation of the immune status and the serum calcium level of patients with known type B interruption and to assess parathyroid function. If urgent surgery is needed prior to investigations confirming the full spectrum of DiGeorge's syndrome, irradiated blood should be used to avoid graft-versus-host reaction. DiGeorge syndrome is addressed in further detail in Chapters 144 and 150.

PHYSIOLOGY

Interrupted aortic arch associated with ductus arteriosus is one of several malformations in which flow through the ductus arteriosus is uniformly reversed. Signs of heart failure usually occur in the early newborn period and deterioration is often rapid. As the ductus constricts, more blood is forced into the lungs, causing pulmonary edema, and less blood enters the descending aorta, resulting in low cardiac output with poor perfusion, shock, metabolic acidosis, and renal failure. Associated defects may create other alterations in blood flow patterns and other life-threatening sequelae.

CLINICAL FEATURES

Infants generally appear well at birth with pulses equal in all extremities in the presence of a widely patent ductus arteriosus with right-to-left flow. Infants can become critically ill and moribund rapidly with ductal closure. The lesion is characterized by early onset of symptoms and death from congestive heart failure

in the first days or weeks of life. Associated lesions may dominate the clinical picture. Differential cyanosis resulting from reversal of flow through the ductus arteriosus is the exception rather than the rule. This finding can be explained by the presence of the VSD allowing left-to-right shunting at the ventricular level so that the pulmonary artery saturation approaches that in the ascending aorta to the extent that upper body and lower body saturations are similar. A saturation difference of at least 10 to 15% must exist before differential cyanosis can be recognized clinically. Measurable differences in oxygen content can be found in spite of clinically inapparent differential cyanosis. When the ductus is widely patent, little or no blood pressure gradient may be measurable between the right upper extremity and lower extremity (Fig. 80–24). With constriction of the ductus, the expected pulse differential should be sought. It can be difficult to note a pulse difference when cardiovascular shock supervenes. A murmur is usually present in older children when subvalvular aortic stenosis or aortic stenosis coexists. No murmur is generated by the right-to-left ductus when widely patent. The VSD is usually nonrestrictive and not the source of a murmur. If a murmur and thrill are present, these are suggestive of additional defects. Ventricular arrhythmias have further complicated the course of some of these ill infants. The role of ductal dilation with prostaglandins is now a valuable adjunct to clinical management in conjunction with the more standard treatment for congestive failure and pulmonary edema.[71]

The chest roentgenogram almost invariably shows cardiac dilation and pulmonary congestion, neither of which is specific for this entity. Absence of the thymus may be suspected when the mediastinum is narrow. The ECG may be normal or may display right ventricular hypertrophy, left ventricular hypertrophy, or biventricular hypertrophy. The hypocalcemia accompanying aortic arch interruption with DiGeorge's syndrome prolongs the corrected QT interval. Echocardiography in the hands of an experienced operator has the potential to provide accurate noninvasive diagnosis of aortic arch interruption, but this is not an easy malformation to diagnose with echocardiography.[120] It is striking that the absence of the thymus gland makes imaging more difficult, because the presence of the thymus enhances technical aspects of recording. It is easy to recognize a discrepancy between the size of the great vessels with a small aorta and a large pulmonary artery. A ductus can be visualized continuing uninterrupted from the pulmonary artery to the descending aorta. From the suprasternal notch the ascending aorta has a straight course to the brachiocephalic vessels. In the most common type B form the aorta appears to end at the left common carotid artery with no suggestion of a transverse arch. One must be careful not to mistake the continuation of the main pulmonary artery, ductus, and descending aorta for a normal aortic arch. Further recognition of a malalignment VSD (visible on the long-axis view) and displacement of the infundibular septum with subaortic narrowing are often identified. The echocardiogram is also useful in assessing prostaglandin therapy for ductal dilation. The use of echocardiography for preoperative diagnosis without further angiography is being explored based on the confident diagnosis of interrupted aortic arch by a skilled examiner. The option for omitting catheterization in an extremely ill infant with poor renal function, thus eliminating the need for contrast material, expands the benefit of accurate noninvasive diagnosis.

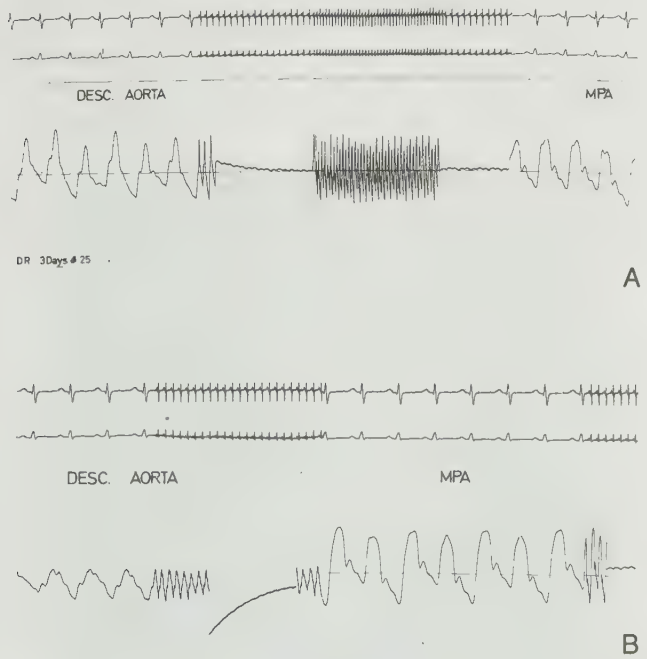

Fig. 80–24. Interrupted aortic arch-effect of prostaglandin E_1 (PGE_1) infusion on ductal patency (see text). Pressure recordings during catheterization. (A) Withdrawal pressure from descending aorta (DESC. AORTA) to main pulmonary artery (MPA) during PGE_1 infusion with ductus widely patent and no pressure gradient between the great vessels. (B) PGE_1 infusion stopped. Ductal constriction has occurred and there is a decrease in pressure in the descending aorta with a significant increase in MPA pressure as well as the pressure gradient between MPA and descending aorta.

CATHETERIZATION AND ANGIOGRAPHY

Catheterization is usually undertaken with the correct clinical impression including knowledge of the associated VSD and PDA. The infant is stabilized medically before catheterization. It is difficult to overemphasize the advantages gained with the use of prostaglandin therapy. In carrying out the procedure, it is important to enter all four heart chambers and the great vessels. If it is difficult to enter the aorta prograde across the VSD, the left ventricle can be entered by way of the mitral valve with a balloon catheter which is then inflated and floated into the ascending aorta. A catheter passed out the pulmonary artery generally passes preferentially across the ductus to the descending aorta. This latter catheter course does not distinguish aortic arch interruption from severe coarctation or widely patent ductus arteriosus in association with other defects. A catheter inserted in the umbilical artery cannot be passed retrograde around the arch, entering instead via a patent ductus and the pulmonary artery. Ventricular injections reveal hypoplasia of the aorta compared with the dilation of the pulmonary artery (Fig. 80–22A). It should be recognized that even large injections of contrast material delivered rapidly into a ventricle may fail to give accurate delineation of aortic arch anatomy. Best visualization of the detailed anatomy of interrupted aortic arch is obtained by injection directly into the ascending aorta. It is impossible to distinguish complete interruption from atresia of the aorta, in which a fibrous band connects the ascending and descending aortas. This distinction is not of practical value con-

sidering that the surgical approach would be the same. One may choose to employ catheterization primarily for detailed examination of the morphology of the aortic arch in a critically ill newborn and rely on echocardiographic definition of the VSD to avoid additional injections. When the decision is made to accompany repair of the interrupted aortic arch with pulmonary artery banding, the additional characterization of the VSD with angled angiographic injections can be postponed until a later catheterization. If the VSD is to be repaired at the same operation, complete characterization of the VSD will be necessary. Prostaglandin infusion should be carefully maintained during catheterization and surgery, to lessen the risks of these procedures.

NATURAL HISTORY

Patients with interruption of the aortic arch usually die early in infancy.[122] Only recently has this high mortality been improved with early recognition and prompt institution of prostaglandin therapy allowing stabilization of the infant to an extent where surgical therapy can be performed under favorable conditions. Long-term followup is not available in most instances, but the present survival of patients to midchildhood is encouraging. The additional burden of possible immune disorders and other serious birth defects correlated with DiGeorge's syndrome may pose more difficult problems than the congenital heart defect.

THERAPY

Medical therapy is rapidly instituted when a patient is thought to have interrupted aortic arch; it consists of prostaglandin infusion to dilate the ductus arteriosus and maintain perfusion to the lower body. Metabolic acidosis is treated, and its reversal can be achieved with bicarbonate as well as by improving perfusion. Improved pulses, reversal of anuria, and correction of acidosis can be dramatic when prostaglandin infusion is begun. Immediate therapy also involves correction of hypocalcemia as well as the anticipation of possible immune disorders by using only irradiated blood to prevent graft-versus-host disease if the possibility of DiGeorge's syndrome is entertained before confirmation is available. Pulmonary edema is treated with diuretic therapy and positive pressure ventilation. Digoxin therapy is reserved for patients who have demonstrably poor ventricular contractility on echocardiogram. Treatment of ventricular tachycardia has been required in some patients with simultaneous attempts to correct electrolyte abnormalities and metabolic acidosis.

Surgical Therapy

The goal of surgery is to restore continuity between the ascending and descending aorta by one of several techniques. The principal limitation to surgical outcome is the condition of the patient at the time of operation. Many centers limit the initial surgery to restoration of continuity of the aorta with pulmonary artery banding from a left chest approach, and prefer not to add the additional repair of the often complex VSD at the initial stage.[134] Repair of the interrupted arch may be accomplished by direct aortic anastomosis, turnup or turndown of one of the arch vessels to bridge the gap, or interposition of a prosthetic graft (Fig. 80–22B). Selected patients with type B interruption have tolerated left carotid turndown to the distal aorta without cerebral insult. Alternatively, the left subclavian artery, if not small, may be brought up and anastomosed to the upper portion of the aorta. With type A interruption, the left subclavian artery arising proximal to the obstruction can be brought down in an end-to-side fashion to the descending aorta. The use of ductal tissue in any repair is considered to be unwise owing to the tendency for ductal tissue to constrict and narrow any anastomosis. Surgeons who prefer a single stage correction perform the operation with deep hypothermia, often by way of a midline sternotomy.[136–138] There is the potential for ample mobilization of the aorta to the level of the diaphragm, which allows the distal aorta to be anastomosed to the upper aorta; some surgeons claim that undue tension on the anastomosis can be avoided by use of this technique. Cardiopulmonary bypass is used for VSD closure; however, the complex location of many VSDs in association with aortic arch interruption makes early VSD closure more difficult. The combined early and late mortality from the one-stage repair has been reported to be 18 to 42%. The combined postoperative mortality after two-stage repair varies widely and is estimated to be between 35 and 72%. Further comparison of these methods should be made. Patient selection should be deliberate based on full knowledge of the variables in individual anatomy.[137]

FOLLOWUP AND OUTCOME

Infants born with interrupted aortic arch are now surviving into midchildhood, providing some perspective on followup. In all cases, it seems to be the associated malformations that dominate the clinical course. A longer period of followup may allow further evaluation of the repair of the interrupted arch itself. Reoperation for debanding and VSD repair in itself carries an additive mortality with the additional risk of complete AV block due to the extensive

Fig. 80–25. A mycotic aneurysm has developed after staphylococcal sepsis in a 6-week-old infant who had previously undergone repair of interrupted aortic arch, type B. At repair, the left carotid artery was turned down to the descending aorta and a pericardial patch was used to enlarge the anastomotic site.

approach required to close the VSD. Repairs using turndown of the carotid artery for reconstruction appear to be tolerated well on shortterm observation, with cerebral flow through the circle of Willis preserved; however, more prolonged evaluation is necessary. In most cases emergency repair of interrupted aortic arch in infancy is palliative owing to the small structures involved especially when interposition grafts are required. By early childhood gradients of at least moderate degree are measurable across reconstruction sites, and limited application of catheterization dilation procedures has been offered in this age group. For instance, it may be advantageous to relieve the moderate restenosis at the time of a catheterization prior to cardiopulmonary bypass, VSD closure, and pulmonary artery debanding with the hope of avoiding a second incision at the time of intracardiac repair that would allow inspection of the previously operated interrupted arch. It should be expected that revision of the interrupted arch will then be necessary in late childhood or after puberty if balloon dilation procedures do not provide sustained relief of residual obstruction. Anecdotal comments from a number of pediatric cardiovascular surgical centers suggest that interrupted aortic arch repair is a common cause of infants requiring prolonged (over 6 months) hospitalization after surgery, but this has not been investigated formally.

Subacute bacterial endocarditis prophylaxis is recommended indefinitely for these children. The unfortunate occurrence in an infant of a mycotic aneurysm soon after repair of interrupted aortic arch with carotid turndown has been observed (Fig. 80–25).

Prompt recognition, early successful medical management, and appropriately applied surgical techniques still do not guarantee an uncomplicated future, of course, since restoration of integrity of the aorta is often only the first step in the treatment of a patient with other complex problems. In general, however, infants born with interrupted aortic arch now have a more optimistic outcome.

CHAPTER 81

Pulmonary Stenosis

John P Cheatham

Obstruction of blood flow from the right ventricle to the pulmonary arteries may occur at various anatomic levels. The level of obstruction may be within the right ventricle (intracavitary), at the valve, or above the valve along the pulmonary arterial tree. In the broad sense, ''pulmonary stenosis'' occurs in approximately 20 to 30% of all individuals with congenital heart disease.

In about half of these cases, the ventricular septum is intact. The basic physiologic abnormality of pulmonary stenosis with intact ventricular septum is obstruction of right ventricular output proportional to the degree of narrowing. Although the site and degree of obstruction are important, it is the presence of an intact septum that separates these individuals from patients with associated ventricular septal defect. In this chapter, we will discuss only obstructive lesions with intact ventricular septum, leaving pulmonary stenosis with ventricular septal defect and pulmonary atresia with or without ventricular septal defect to be discussed elsewhere in the book. Furthermore, we acknowledge the confusion among various ill-defined descriptive terms such as ''pure pulmonary stenosis,'' ''isolated pulmonary stenosis,'' and ''uncomplicated pulmonary stenosis.'' We have chosen the anatomic and physiologic term of ''pulmonary stenosis with intact septum'' to be understood and preferred over the anatomic term of ''pulmonary stenosis with normal aortic root'' as described by Abrahams and Wood[1] and later endorsed by Rowe.[2]

In this chapter, the following congenital cardiac defects are discussed: 1) pulmonary valve stenosis, 2) intracavitary obstruction of the right ventricle, and 3) pulmonary artery stenosis, all with intact ventricular septum.

PULMONARY VALVE STENOSIS

Background

Pulmonary valve stenosis comprises approximately 80 to 90% of all those lesions causing obstruction to right ventricular outflow. Initially described by Morgagni in 1761,[3] the pathology of the lesion was subsequently discussed by Meckel.[4] However, it was Fallot[5] who separated seven cyanotic examples of the disorder from 39 cases of the tetralogy and described a morbid term of ''trilogy'' that remains in use today, particularly by the French, to describe pulmonary stenosis, atrial septal defect, and right ventricular hypertrophy. The anatomy of pulmonary valve stenosis was nicely summarized in a monograph by Brock, who defined eight varieties of pulmonary stenosis.[6] Initially, pulmonary valve stenosis was thought to be relatively uncommon. In the first edition of her classic 1947 monograph, Dr. Taussig stated that she had not had the opportunity to study a proven case herself.[7] However, since the introduction first of cardiac catheterization and subsequently of two-dimensional and Doppler echocardiography, we now recognize that pulmonary valve stenosis is a common congenital cardiac defect.[8–13]

Prevalence

A conservative estimate of the prevalence of pulmonary valve stenosis with intact ventricular septum is that it is present in 7 to 12% of children born with congenital heart disease. Abrahams and Wood found an incidence of 11.6% of 689 cases,[1] and Campbell found 10% incidence in 1130 cases of congenital cardiac defects.[14] Rowe reported 9.9% of 15,104 cases at The Hospital

for Sick Children, Toronto, to have pulmonary stenosis.[2] Nadas and Fyler stated that although an incidence of 7.5% was found at Boston Childrens Hospital Medical Center, pulmonary stenosis may be found in up to 10 to 15% of those patients with congenital heart disease who live beyond infancy.[11]

Rose and colleagues reported different seasonal peaks of birth rate in patients with pulmonary stenosis dependent on the gender, males peaking in the fall and females in the spring.[15] Campbell found that 2.2% of siblings of patients with pulmonary stenosis also have a cardiac defect, usually pulmonary stenosis.[16] Nora and colleagues reported the probability of recurrence in siblings of pulmonary stenosis patients to be 2.9%.[17] Familial pulmonary stenosis has also been discussed by Klinge and Laursen.[10]

A recent report by Ackerman and colleagues in patients with hemophilia A supports the hypothesis that pulmonary valve stenosis can be inherited as an X-linked dominant trait.[18] Other reports suggest that dysplastic pulmonary valve stenosis in beagle dogs is not inherited as a simple mendelian trait, but rather from genes at more than one locus.[19] Mallette and associates suggested that there is a positive correlation between transient congenital hypoparathyroidism and pulmonary valve stenosis in neonates.[20]

There have been several studies regarding the incidence of congenital heart disease in offspring of parents with a specific defect and the rate among twins. Nora and Nora reported the incidence of pulmonary valve stenosis in 111 offspring with one parent having pulmonary stenosis to be 3.6%.[21] Obviously, if the mother has a mendelian syndrome such as Noonan's syndrome, half of her children will have this autosomal dominant disease. Since the incidence of congenital heart disease (mostly dysplastic pulmonary valve stenosis) is 50% in these patients, the risk for the offspring would be 25% rather than 3.6%. Finally, Anderson's report of congenital heart malformations in 109 sets of twins and triplets suggests a concordance rate up to 8.3% for monozygotic pairs and 2.2% for dizygotic twin pairs.[22]

Embryology

During cardiac septation, two endocardial cushions within the truncus arteriosus, the intercalated valve cushions, will eventually develop into the anterior cusp of the pulmonary valve and the posterior or noncoronary cusp of the aortic valve.[23] The two posterior cusps of the pulmonary valve and the two anterior or coronary cusps of the aortic valve are derived from the major truncus cushions after they have fused to form the truncus septum.[24]

The exact pathogenetic mechanism responsible for pulmonary valve stenosis is still somewhat difficult to explain. Keith suggested that there was maldevelopment of the distal portion of the bulbus cordis, from which the valves develop.[25] More and coworkers pointed out the difficulty with this theory, since the ventricular septum has already been completely formed, yet somehow a maldevelopment of the bulbus cordis leads to fusion of well-formed pulmonary valve cusps.[26] Brock suggested that there may be an abnormality of the distal bulbus cordis leading to pulmonary stenosis with sparing of the proximal bulbus, which participates in closure of the ventricular septum.[27]

Oka and Angrist have postulated that pulmonary valve stenosis may be a result of fetal endocarditis rather than a pure embryologic maldevelopment.[28] Genetic factors may play an important role. Certainly, the association of pulmonary valve stenosis and supravalve and branch pulmonary artery stenosis with multiple somatic abnormalities has been well documented.[10,17,19,21,29,30]

Anatomy and Pathology

Brock initially described eight varieties of pulmonary stenosis based on anatomic descriptions: 1) stenosis of the pulmonary valve with a normal aortic root, 2) infundibular stenosis with a normal aortic root, 3) pulmonary atresia, 4) tricuspid atresia, 5) tetralogy of Fallot, 6) double-outlet right ventricle with ventricular septal defect and pulmonary stenosis, 7) transposition of the great arteries with pulmonary stenosis, and 8) common ventricle with pulmonary stenosis.[6] Since this classic description, there have been very few studies on the pathologic anatomy of pulmonary valve stenosis. Edwards described the anatomy of the domed-shaped valve.[31] Koretzky and colleagues[32] and later Jeffrey and colleagues[33] described a type of stenosis produced by dysplastic hypertrophy of the pulmonary valve leaflets.

A more recent report by Gikonyo and co-workers beautifully described the gross and microscopic features of the anatomic pathology of 31 autopsy cases of congenital pulmonary valve stenosis.[34] They divided these specimens into six anatomic subgroups:

1) domed: 42%
2) tricuspid: 6%
3) bicuspid: 10%
4) unicommissural: 16%
5) hypoplastic annulus: 6%
6) dysplastic: 19%

In domed pulmonary valve stenosis, the valve resembles a wind sock when viewed from the pulmonary trunk (Fig. 81–1a, b). No separation into leaflets can be identified, and the base of the truncated cone is attached to the arterial trunk. Raphae are usually identified but may be either shallow or tall and variable in number. The size of the orifice varies from a pinhole to several millimeters in diameter. Microscopically, the thickening is due to an increased valve spongiosa, and the normal annulus components are deficient or absent.[34]

The unicommissural pulmonary valve is composed of a large, single leaflet and, as its name implies, has a single commissure (Fig. 81–2). The microscopic sections reveal valve thickening caused by increased fibrosa and spongiosa with the fibrous annulus replaced by myxomatous tissue.[34]

The specimens with bicuspid pulmonary valve have two leaflets and two commissures identified (Fig. 81–3). A slit-like opening of the valve is seen secondary to fused commissures. Microscopically, the leaflets are thickened as a result of increased collagen and elastic tissue, usually arising directly from the wall of the pulmonary trunk. Both the spongiosa and the supravalve annulus are absent.[34]

In tricuspid pulmonary valve stenosis, there is moderate thickening of all three leaflets and fusion of all three commissures. The microscopic section demonstrates thickened leaflets with increases in both collagen and myxomatous tissue and sparse elastic tissue.[34]

The obstruction found in "hypoplastic pulmonary valve and annulus" is due to a combination of narrowed annulus and hypoplastic, rigid leaflets. In contrast to cases with dysplastic valves, both the right ventricular infundibulum below and the pulmonary trunk above are normal. There are three diminutive, rigid leaflets with mild fusion of commissures and a markedly narrowed an-

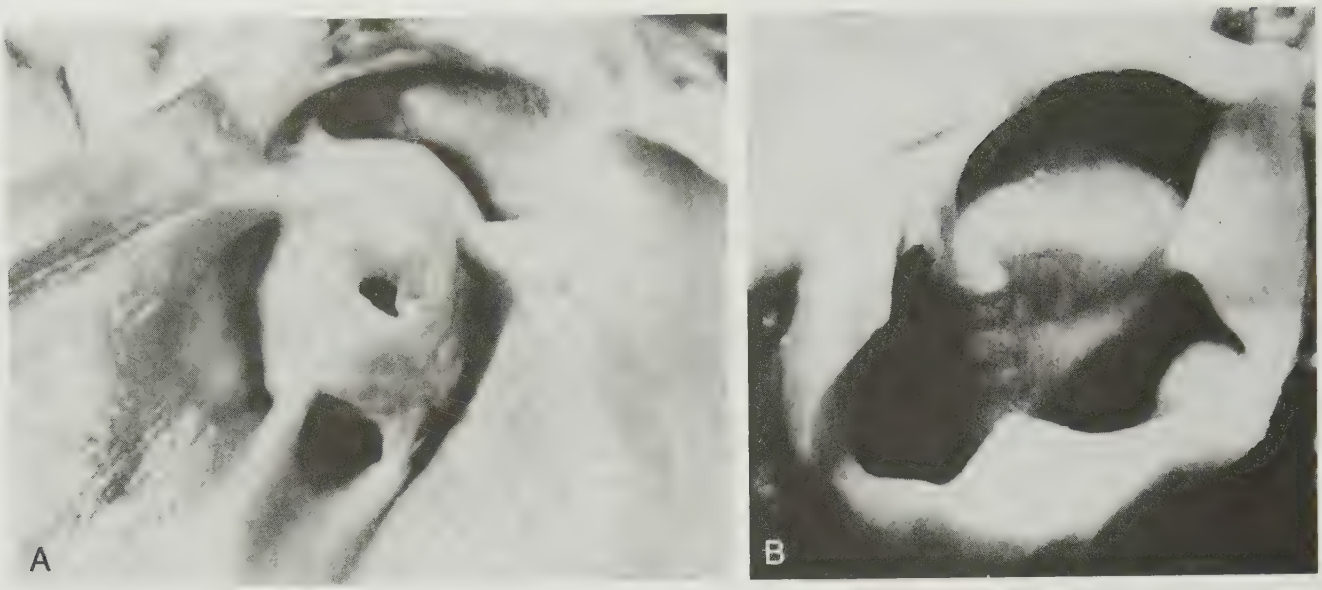

Fig. 81–1. Domed stenotic pulmonary valves in two patients. (A). Pulmonary valve viewed from above in a 21-year-old woman. Four shallow raphae are present. There is no evidence that these raphae represent fused commissures, nor is there other evidence of fusion of valve leaflets. (B). Domed stenotic pulmonary valve in a 16-day-old boy. There is a 1-mm orifice at the apex of the domed valve. Three tall raphae are present. There is no evidence that these represent fused commissures. No identifiable pulmonary valve leaflets are present. (Reproduced with permission from Gikonyo, B.M., Lucas, R.V., and Edwards, J.E.: Anatomic features of congenital pulmonary valvar stenosis. Pediatr. Cardiol., *8*:109, 1987.)

Fig. 81–2. Pulmonary valve viewed from above in a 1-day-old girl with a stenotic unicommissural pulmonary valve. The black probe is in the valve orifice and lies on top of a single commissure. A shallow raphe is present at 12 o'clock. The single valve leaflet is thickened and has a myxomatous appearance. (Reproduced with permission from Gikonyo, B.M., Lucas, R.V., and Edwards, J.E.: Anatomic features of congenital pulmonary valvar stenosis. Pediatr. Cardiol., *8*:109, 1987.)

nulus. Microscopically, the fibrosa and spongiosa components are preserved, while the supravalve annulus is elongated.[34]

Much has been written about dysplastic pulmonary valve stenosis. The gross composition of the valve consists of three markedly thickened, redundant leaflets with unfused commissures (Fig. 81–4). The obstruction to right ventricular outflow is mostly from the mass or bulk of the leaflets as well as a narrowed annulus. There is also narrowing of the right ventricular infundibulum below and the pulmonary trunk above the valve. The microscopic appearance of myxomatous valve tissue with sparse elastic fibers and poorly formed annulus are observed. Dysplastic pulmonary valves may also be present in some apparently nonfamilial cases of pulmonary stenosis and in the majority of patients with Noonan's syndrome.[2,29] Some of the anatomic and pathologic features of dysplastic pulmonary valves and hypoplastic pulmonary annuli may explain recent reports of unsuccessful balloon valvuloplasty and surgical valvotomy, which will be discussed later in this chapter.

The pathologic findings in the remaining portion of the right-sided cardiac structures are caused by secondary changes from the valve obstruction.[35] The right ventricle hypertrophies in response to the increase in afterload and is usually proportional to the degree of obstruction. The infundibular area of hypertrophy is particularly prominent; this often results in significant subvalvular obstruction. The infundibular endocardium may be opaque, with thickening of the tricuspid valve and chordal attachments. The tricuspid valve abnormalities may be the result of the mechanical stress leading to regurgitation of the valve. The right atrium may be dilated from tricuspid regurgitation or thickened from the increased pressure necessary to fill a noncompliant right ventricle. An atrial communication, either patent foramen ovale or atrial septal defect, is commonly found.

In severe pulmonary valve stenosis, small areas of myocardial

Fig. 81–3. Bicuspid stenotic pulmonary valve in a 41-year-old man who had a pulmonary valvotomy performed six years previously. The valve is viewed from above. The site of transection of the valve, outflow tract and pulmonary artery done at autopsy is noted at 2 o'clock. At the time of operation, the fused commissures were cleanly incised into the wall of the pulmonary artery. In the six years following the operation, the pulmonary valve leaflets separated considerably at the site of their original surgical incision. The two valve leaflets are thickened. The patient had no evidence of residual pulmonary valvar stenosis during life and died of hypertensive cardiovascular disease. (Reproduced with permission from Gikonyo, B.M., Lucas, R.V., and Edwards, J.E.: Anatomic features of congenital pulmonary valvar stenosis. Pediatr. Cardiol., *8*:109, 1987.)

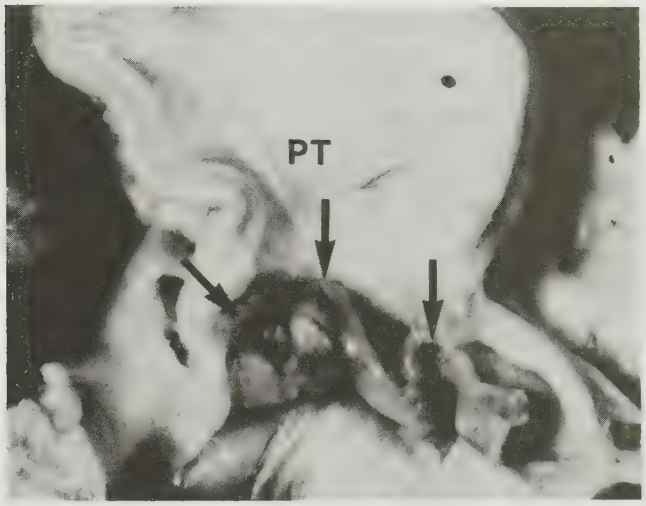

Fig. 81–4. Dysplastic pulmonary valvar stenosis in a four-month-old girl. The pulmonary trunk, pulmonary valve, and right ventricular infundibulum have been opened. The valve leaflets are thickened and completely filled the right ventricular outlet before it was opened. The arrows depict the commissures that are not fused. Note also that the pulmonary trunk is significantly narrowed just above the pulmonary valve. PT = pulmonary trunk. (Reproduced with permission from Gikonyo, B.M., Lucas, R.V., and Edwards, J.E.: Anatomic features of congenital pulmonary valvar stenosis. Pediatr. Cardiol., *8*:109, 1987.)

infarction involving the subendocardium of the right ventricular free wall and papillary muscles have been reported at autopsy.[36] This histopathologic abnormality may be more frequently found than is clinically suspected, particularly in critically ill infants with pulmonary stenosis. In sick infants with an associated large atrial shunt, the left ventricle may show significant hypertrophy.[37] However, many patients with pulmonary valve stenosis have a left ventricular dimension that is normal or increased in size. When a right aortic arch is present with pulmonary stenosis, one should be highly suspicious of a variant of tetralogy of Fallot.[38]

In the majority of patients with pulmonary valve stenosis, the main pulmonary arterial trunk is dilated with evidence of a "jet" lesion. The exception to this is in children with dysplastic pulmonary valve stenosis, in which there is usually no poststenotic dilatation. The proximal left pulmonary artery may occasionally be involved with this process. Two different mechanisms are proposed to explain this poststenotic dilatation: one involving the physics of flow dynamics, the other suggesting an intrinsic histopathologic abnormality. The more accepted mechanism states that the dilation is related to the high velocity of right ventricular output ejected through a narrowed aperture.[39,40] Using the laws of physics, the kinetic energy resulting from this high velocity must be converted to distending lateral pressure. During this process, "eddy currents" of high and low pressure occur, causing structural fatigue and stress of the elastic wall of the pulmonary artery.[41] This process may require a long period of time for dilation to occur and may explain why some newborns with significant pulmonary valve stenosis do not have poststenotic dilatation of the pulmonary trunk at birth yet develop a dilated main pulmonary artery several months later.

It is important to remember that the degree of poststenotic pulmonary trunk dilatation is frequently not proportional to the degree of pulmonary valve obstruction. In other words, patients with only mild pulmonary valve stenosis may have extremely dilated pulmonary trunks and vice versa. Therefore a second mechanism has been postulated: the poststenotic dilatation may be the result of a distinct and intrinsic abnormality of the pulmonary arterial wall. However, as in those patients with absent pulmonary valve syndrome, no definite abnormality of the pulmonary trunk has been consistently demonstrated.

Pathophysiology

The principal physiologic consequence of pulmonary stenosis with intact ventricular septum is an elevation of right ventricular pressure as a result of obstruction to right ventricular cardiac output. This rise in pressure leads to right ventricular hypertrophy that is proportional to the degree of obstruction. As a practical

matter, it is helpful to separate pulmonary valve stenosis physiology into two types: severe and mild-to-moderate.

The work of Rudolph allowed us to improve our understanding of the fetal physiologic abnormalities of pulmonary stenosis.[42] As the obstruction develops, an increase in right ventricular muscle mass occurs (from both hyperplasia and hypertrophy of the muscle fibers) that is proportional to the severity of stenosis. The fetal or neonatal response to an increase in afterload is apparently different from that of the adult myocardium. The mature animal myocardium usually hypertrophies in response to obstruction with very little hyperplasia noted. Since hypertrophy of the myocardial cell is not associated with an increased number of capillaries and hyperplasia is associated with capillary growth, one can speculate how the fetal or neonatal myocardium has several advantages over the adult myocardium. In the immature animal, the relationship between the myocardial cell and capillaries remains constant; this may allow the individual the ability to generate high ventricular pressure that maintains normal cardiac output across severe obstruction.[42]

There are a few hemodynamic characteristics worthy of discussion that clearly distinguish pulmonary valve stenosis with intact ventricular septum from other types of right ventricular outflow tract obstruction, such as tetralogy of Fallot. In the patient with an intact septum, the pressure generated in the right ventricle may be higher than that in the left ventricle. In addition, for a comparable degree of pulmonary stenosis, patients with an intact septum may be able to establish better pulmonary flow with better exercise tolerance than do children with tetralogy of Fallot.[11] The limiting factor to increasing cardiac output appears to be the noncompliant right ventricle, which is unable to fill, thus limiting output.

The pressure rise during right ventricular contraction occurs progressively to an early systolic peak followed by a fall in pressure. Since emptying of the right ventricle depends upon the amount of resistance at the orifice in patients with pulmonary valve stenosis, the peak of contraction occurs later in systole as the severity of obstruction increases. Normal cardiac output is maintained at the expense of right ventricular hypertrophy. Clinically, right-sided heart failure with right ventricular dilatation is seen in two separate groups of patients. It may occur in newborns with critical pulmonary valve stenosis who are unable to cope with the cardiac demands of the body. Right heart failure is also seen in rare individuals who are not recognized to have severe pulmonary valve stenosis with right ventricular hypertrophy. Eventually, usually in early adulthood, right ventricular dilatation may occur with subsequent congestive failure. Pulmonary flow decreases with right ventricular failure, but systemic oxygenation may be normal at rest. With an increase in cardiac demand, such as with exercise, symptoms of right-sided congestive heart failure occur. Cyanosis is a relatively late occurrence in these patients and may be the consequence of one or two mechanisms. It may be secondary to greatly diminished cardiac output and an increased oxygen extraction at the capillary level or the result of a right-to-left shunt at the atrial level. The atrial right-to-left shunt depends upon the increase in right atrial pressure as a result of decrease in right ventricular compliance with an increase in end-diastolic ventricular pressure. It is noteworthy that in experimental animal studies, right-sided failure occurred only when the diameter of the pulmonary artery was reduced to less than one third of its original size.[43]

Williams and colleagues described a syndrome of underdeveloped right ventricle with pulmonary stenosis that may present as cyanosis in the neonate.[44] Because of the hypoplastic right ventricle, the compliance of the ventricle is decreased with subsequent right-to-left atrial shunting.[10,44–47] Right ventricular compliance may be decreased by endocardial fibrosis as a result of subendocardial ischemia documented in a few infants with severe pulmonary valve stenosis.[36] With the altered right ventricular compliance found in severe pulmonary stenosis, a tall, peaked A wave is often seen in the right atrium. It is also important to remember that in many patients with severe pulmonary valve stenosis and intact ventricular septum, tricuspid insufficiency occurs. This physiologic event may alter right atrial pressure, with a large V wave and an increase in mean pressure, with subsequent effects on cardiac output and symptoms depending on the presence or absence of an interatrial communication.

Manifestations

Clinical Features

Clinically, pulmonary valve stenosis with intact ventricular septum is best described as either mild-to-moderate or severe. Rowe reported equal frequency of both grades.[2]

Mild-to-Moderate Stenosis. Patients with mild pulmonary valve stenosis are asymptomatic, while some individuals with moderate stenosis may later develop mild dyspnea and fatigue with exertion. Growth and development in these children are usually normal unless a significant associated cardiac defect is present. Cyanosis is absent in individuals with mild pulmonary stenosis and rare in those with moderate obstruction. It is worthwhile to note that cyanosis is not a reliable criterion for assessment of severity in pulmonary stenosis.

The jugular venous pulse is usually normal, and there are no signs of congestive heart failure. The precordium is quiet, with a palpable systolic thrill rarely present. A few patients demonstrate a tapping right ventricular–type impulse. The physical appearance of the children is usually normal, although 20% of the patients in the Toronto series demonstrated the moon facies and chubby features previously described by Wood.[2,48]

The striking auscultatory feature of pulmonary valve stenosis is a prominent systolic, ejection-type murmur. The murmur may vary in length and intensity, but it usually ends before the aortic valve closure. The maximum intensity of the murmur is at the upper left sternal border radiating to the back; the murmur is also heard along the precordium and neck. The phonocardiogram demonstrates a crescendo–decrescendo characteristic with a peak in mid- to late systole depending on the severity (a later peak with more severe stenosis) and with a medium or high frequency.[49–51] The duration of the murmur in mild stenosis is shorter with a peak that seldom passes midsystole. In contrast, patients with tetralogy of Fallot with severe stenosis also have a short systolic ejection murmur that peaks early in systole. The murmur of pulmonary valve stenosis increases in duration and intensity after inhalation of amyl nitrate (or other vasodilating agents), whereas the opposite is true in children with tetralogy of Fallot.[52] It is also important to remember that patients with combined moderate infundibular and valvar pulmonary stenosis may also have a systolic ejection

murmur along the fourth intercostal space as well as in the usual higher location. A soft, early, decrescendo diastolic murmur may infrequently be heard in the second left interspace and represent mild pulmonary regurgitation. More likely, a low-frequency mid-diastolic murmur over the tricuspid or mitral valve may be heard; this should heighten suspicion of an associated large atrial or ventricular septal defect, respectively.

A high-pitched ejection sound or systolic click is usually heard in mild-to-moderate pulmonary valve stenosis. It is frequently heard along the second or third left intercostal space, but it may also be audible along the lower sternal border.[53] This sound usually occurs early in systole, 0.08 s after the Q wave, and may be confused with wide splitting of the first heart sound.[54,55] It can usually be distinguished by its sharp, high-pitched quality, by the location, and by the click becoming louder during expiration. The click sound most likely originates from the sudden opening and doming of the thickened but compliant stenotic valve found in mild-to-moderate stenosis.[53] An alternative mechanism of etiology, but one that is less accepted, is the sudden expansion of the pulmonary arterial wall.[53,56] An inverse relationship between severity and the Q–click interval on the phonocardiogram has been found:[57] as the severity increases, the systolic ejection click occurs earlier, to the point at which it may be indistinguishable from the first heart sound. Important correlations of respiratory changes in the click to severity have been made.[53] Hultgren found that when the diastolic pressure of the pulmonary arteries consistently exceeded the right ventricular end-diastolic pressure, a click was present in all phases of the respiratory cycle. In contrast, if the right ventricular end-diastolic pressure exceeded the pulmonary artery diastolic pressure during inspiration, no click was recorded. Later, Weyman and colleagues' echocardiographic work supported these observations.[58]

The second heart sound in children with mild-to-moderate pulmonary valve stenosis is usually split and of normal intensity. The degree of splitting is directly proportional to the severity of obstruction. This correlation between degree of stenosis and width of splitting of the second heart sound was demonstrated by phonocardiograms and simultaneous right ventricular pressure measurements.[50,55] Thus in patients with mild-to-moderate stenosis, the second sound varies normally with respiration. A fixed, widely split second heart sound with mild pulmonary valve stenosis should alert one to the possibility of an associated atrial septal defect.

There also appears to be an inverse relationship between the severity of stenosis and the intensity of the pulmonary component of the second sound.[50,55] As the severity of the pulmonary valve stenosis increases, the intensity of the closure sound of the pulmonary valve decreases. Occasionally, in mild stenosis with markedly dilated main pulmonary artery, the pulmonary closure sound may actually be louder than normal.[59,60] The first heart sound is unremarkable, and the blood pressure and peripheral pulses are usually normal in children with mild-to-moderate pulmonary valve stenosis.

Severe Stenosis. Conventionally, severe pulmonary valve stenosis usually implies a resting right ventricular pressure equal to or greater than left ventricular pressure or a transvalvular gradient exceeding 80 mm Hg. Most patients in this group have signs or symptoms, although up to 25% are asymptomatic.[2] Central cyanosis is one of the most important signs in patients with severe stenosis and some form of atrial communication.[61,62] However, mild peripheral cyanosis may be present in severe obstruction with intact atrial septum and low cardiac output.[14,63] The central cyanosis depends to a large extent on the amount of right-to-left atrial shunting. Most patients with an atrial communication can be demonstrated to have some degree of right-to-left shunting at rest or with exercise by indicator dye dilution curves, contrast echocardiography, or pulse-oximetry. In the Toronto series, two thirds of children with severe pulmonary stenosis had right-to-left atrial shunting.[2] However, only 15% were moderately or markedly cyanosed, and 20% had clubbing of the fingers. At least during the childhood years, clinically apparent and significant central cyanosis and clubbing is unusual, although a small degree of central right-to-left shunting is common in these patients.

It has been postulated that the degree of central cyanosis may be progressive with age if the relative size of the shunt increases. Campbell found that 10% of 44 cyanotic patients with severe pulmonary valve stenosis and intact ventricular septum were cyanotic at birth, while 25% were cyanotic by four years of age, the remainder becoming cyanotic later in life.[14] In this group, the average age of onset of cyanosis was 14.4 years. In the Toronto series, 25% were cyanotic at birth, 50% by one year of age, and 67% by five years.[2] Although squatting has been reported, most of these cases have subsequently been diagnosed to have tetralogy of Fallot. Therefore squatting as a principal symptom of severe pulmonary valve stenosis with intact ventricular septum should be scrutinized, and other forms of congenital heart disease should be considered.

Children with severe pulmonary stenosis may have dyspnea and fatigue even with a moderate degree of exercise. All of the cyanotic patients in the Toronto series exhibited exertional dyspnea.[2] In older patients, episodes of chest pain and syncope have occurred with exercise.[1,14,64] Marquis reported an instance of sudden death in a patient with severe pulmonary valve stenosis.[65] In another report, a 3½-year-old child complained of epigastric pain after exercise and subsequently died from right ventricular free wall and septal infarction.[66] Many of the symptoms in this group of patients are related to critically low cardiac output during exercise and inadequate myocardial blood flow. It is possible that this pathophysiologic process may lead to cardiac arrhythmias.[2]

Growth and development in infants with severe pulmonary stenosis are usually normal, without evidence of wasting. In the Toronto series, 50% of patients with severe pulmonary stenosis have the moon facies and chubby phenotype.[2,48] It is wise to remember that moon facies is a common finding in healthy-appearing, normal children and is not a pathognomonic feature of pulmonary valve stenosis.

Prominent A waves in the jugular venous pulse are frequently seen in patients with severe pulmonary valve stenosis. These pulsations may be palpated in the liver as well but are not a consistent finding. In cases with right-sided failure secondary to severe pulmonary stenosis, a prominent V wave in the jugular venous pulse may overshadow the A wave and represent significant tricuspid valve insufficiency.

Precordial palpation may demonstrate evidence of cardiomegaly in patients with severe pulmonary valve stenosis and cardiac decompensation. The apical beat is tapping in quality with a right ventricular heave. Abrahams and Wood placed a great deal of importance on this sign, since it is lacking in moderate cases of

pulmonary stenosis or in patients with tetralogy of Fallot.[1] Later, Schmidt and Craige quantitated this observation in children.[67]

A systolic thrill is almost always palpated in the pulmonic area but may also be felt in the suprasternal notch, in the left carotid artery, and even along the lower sternal border. The systolic thrill may be absent in very young infants with severe pulmonary valve stenosis and in those with congestive heart failure and low cardiac output. Radiation of the thrill into the neck has led to a mistaken clinical diagnosis of aortic stenosis on occasion.

The systolic murmur of severe pulmonary valve stenosis is maximal at the second and third left interspaces, radiating to the back, neck, and rest of the precordium. The murmur is usually loud, harsh, and long in quality. In severe stenosis, the peak occurs later in systole. It is generally true that the murmur of severe stenosis is loud. Dimond and Lin found no relationship between the murmur's intensity and peak right ventricular pressure.[66] Mannheimer and Jonsson later disputed this finding,[68] and the Toronto series reported that no infants dying with severe pulmonary valve stenosis had less than a grade 3 systolic murmur.[2] In young infants with severe stenosis and congestive heart failure, the systolic murmur of tricuspid insufficiency may predominate, with very little murmur noted over the pulmonary area.

When the systolic ejection click occurs earlier, it signifies more severe stenosis. Many times, this ejection sound cannot be separated from the first heart sound. The first sound is usually normal. In severe stenosis, it is difficult to assess the respiratory splitting of the second heart sound. When the obstruction is critical, the second sound is not audible at the left upper sternal border, the aortic component being obscured by the long systolic murmur and the pulmonic sound being too soft to be clinically apparent. Various investigators have found a combination of the Q–ejection click interval, Q–peak magnitude of the murmur, and semilunar valve closure interval to be very useful in estimating the severity of right ventricular hypertension by noninvasive means.[55,57] This is currently of limited practical applicability because of the use of continuous-wave Doppler estimation of severity of pulmonary valve stenosis, which is discussed later in the chapter.

It is sometimes difficult to make clinical estimates of the severity of pulmonary valve stenosis in patients with Noonan's syndrome or, more specifically, in individuals with dysplastic pulmonary valves. The redundancy of the tissue usually abolishes the systolic ejection click and also alters splitting of the second sound. Therefore one has to be very careful about assessing severity of stenosis in these individuals.

Electrocardiogram

The electrocardiogram has been used extensively in the assessment of severity in patients with pulmonary valve stenosis.[2,11,35,57,69–72] In mild stenosis, the electrocardiogram may be normal in 30 to 65% of individuals.[1,66,73,74] Frequently, the only abnormality is a slight rightward deviation of the mean QRS frontal plane axis. The R wave in the right precordial leads usually is less than 10 to 15 mm. Both Ellison and Restiaeux[70] and Fowler and colleagues[71] have shown that QRS conduction delay is characteristic of mild pulmonary stenosis. These authors also showed that only 4% of patients with mild stenosis have complete right bundle branch pattern. The P and T waves are usually normal.

A normal electrocardiogram in moderate pulmonary valve stenosis is the exception, being present in only 10% of cases.[35] There tends to be some right axis deviation and inversion of the R/S ratio in V_1. The R wave is usually less than 20 mm with an R/S ratio greater than 4/1 (Fig. 81–5). The P waves are usually normal. Approximately 50% of patients have upright T waves in the right precordial leads.

The electrocardiogram is almost always abnormal in patients with severe pulmonary stenosis, with very few exceptions. There may be extreme right axis deviation, frequently greater than 150°. In the right precordial leads, a qR, Rs, or a pure R wave is usually present, the magnitude of the R wave being greater than 20 mm (Fig. 81–6). The R/S ratio in V_1 is reversed, while the R/S ratio in V_6 may be less than 1.0 in severe stenosis. The P waves are abnormally tall and peaked in lead II and the right precordial leads, indicative of right atrial enlargement. The T waves may be upright or inverted in the right precordial leads with occasional ST changes suggestive of ischemia.[57]

Before Doppler echocardiography was routinely available, the

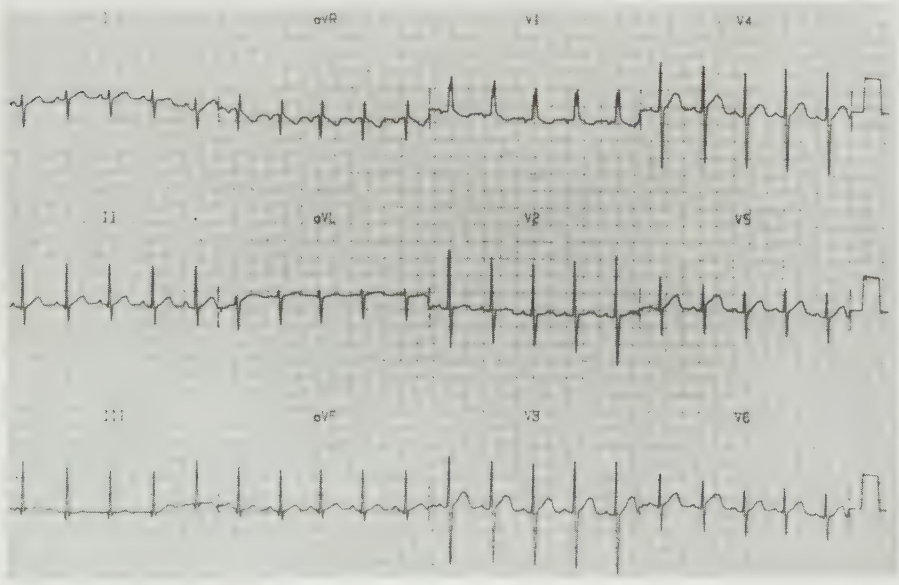

Fig. 81–5. An electrocardiogram in a four-year-old girl with moderate pulmonary valve stenosis. Right axis deviation (QRS axis of +120°) and right ventricular hypertrophy are frequently seen. As in this case, the R wave is usually less than 20 mm in lead V_1 with an R/S ratio greater than 4/1. The T waves are flattened in V_1 but are upright in V_2.

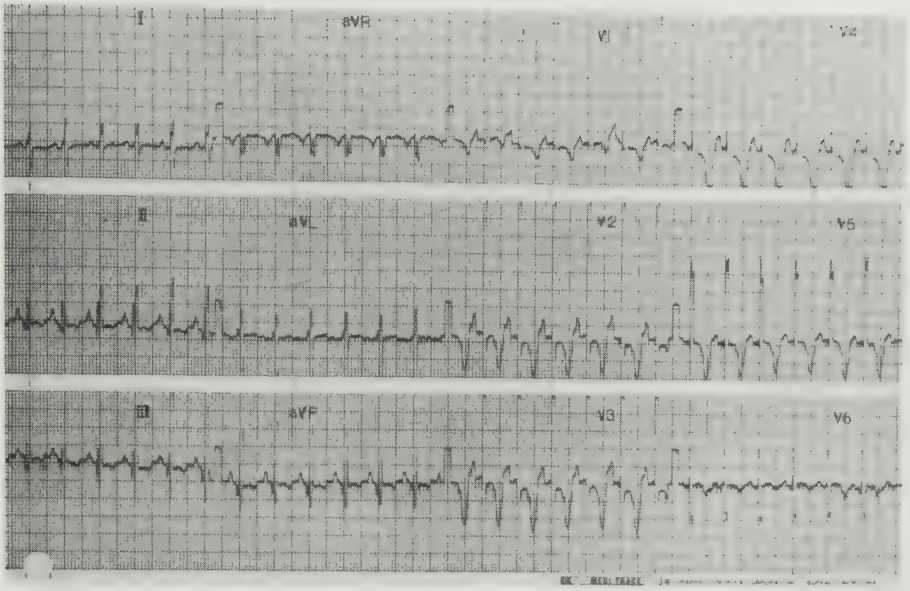

Fig. 81–6. An abnormal electrocardiogram in a three-day-old with severe pulmonary valve obstruction. A qR pattern is observed in lead V_1 with an R wave greater than 20 mm, indicating significant right ventricular hypertrophy. Although not present in this case, T waves and ST segments may suggest ischemia.

resting right ventricular pressure was estimated by using the electrocardiogram of patients between 2 and 20 years old with pulmonary valve stenosis:[42] RV pressure in millimeters of mercury equals the R wave amplitude (in millimeters) in V_4R or $V_1 \times 5$ if a pure R wave is present. Predictive equations also have been developed by using data obtained during the U.S. Joint Study of Congenital Heart Defects.[75,76] As expected, the most important variables were the auscultatory findings and the electrocardiogram. An estimation of the pressure gradient across the pulmonary valve was given by the following equation:

$$\text{Pressure gradient right ventricle to pulmonary artery (mm Hg)} = 10.5(\text{ISM}) + 2.6(S_1) + S_2 \text{ score} + \text{T score}$$

where ISM = intensity of systolic murmur graded 1 to 6; S_1 = S wave in lead I in millimeters, where 1 mm = 0.1 mV; S_2 score = -10 if P_2 is normal, $+2$ if P_2 is audible but diminished, and $+15$ if P_2 is inaudible; T score = $+15$ if T wave in V_1 is diphasic when R wave in V_1 is greater than 10 mm, otherwise the T score = 0. The above equation is seldom used today to assess the severity of pulmonary valve stenosis, but the informal judgment of severity in the clinic takes these variables into consideration in a less quantitative manner.

Occasionally, infants or newborns with severe pulmonary valve obstruction have a QRS axis that is more "leftward" than expected, between 30° and 60°, with left ventricular hypertrophy and right atrial enlargement.[77] In the older patients discussed by Williams and colleagues, more left ventricular voltage and less right ventricular hypertrophy were found in patients with underdeveloped right ventricles.[44] Ellison and Restiaeux reported the association of left axis deviation with superior frontal plane loop in some patients with pulmonary stenosis.[70] It is unclear from the report whether there is a direct relationship between this electrocardiographic abnormality and Noonan's syndrome, associated cardiomyopathy, or possibly an associated endocardial cushion defect.

Chest Roentgenogram

The roentgenographic features of pulmonary valve stenosis with intact ventricular septum have been well described by various authors.[2,12,78–84] The most consistent and distinctive radiographic feature is a prominent main pulmonary artery segment secondary to poststenotic dilatation of the pulmonary trunk and proximal left pulmonary artery (Fig. 81–7). This finding is present in up to 90% of patients with pulmonary valve stenosis, but it may be absent in infants, small children, and patients with dysplastic pulmonary valves.[9,33] The cardiac apex is usually down-pointing and rounded. Only rarely in severe obstruction without failure is uptilting noted. The right cardiac border is not suggestive of right atrial enlargement, except in severe cases with tricuspid insufficiency or moderate obstruction with atrial septal defect. However, in one series, up to 50% of patients with pulmonary stenosis were found to have prominence of the right atrial segment.[35] The aortic arch is almost always left-sided, and the left atrial shadow is normal.

In cases of mild-to-moderate pulmonary valve stenosis, the heart size and pulmonary vascular markings are usually normal. If there is severe obstruction without cardiac decompensation, there may only be mild cardiac enlargement. When right-sided cardiac failure occurs, the chest roentgenogram demonstrates cardiomegaly with a "globular-shaped" heart, prominent right atrial shadow, and diminished pulmonary vascular markings (Fig. 81–8). Pulmonary vascularity is seldom increased unless there is a significant left-to-right shunt at the atrial, ventricular, or ductus arteriosus level. Decreased pulmonary vascular markings may be found in severe cases with a right-to-left shunt.

Echocardiogram

The noninvasive evaluation of abnormalities of the pulmonary valve by M-mode and two-dimensional echocardiography was less than satisfactory in the past.[58,85] However, with the recent advances in imaging capabilities, Doppler echocardiography, and color flow mapping techniques, the sensitivity and specificity in detecting valvular abnormalities have drastically improved.[86–99]

M-mode. M-mode echocardiography can help diagnose pul-

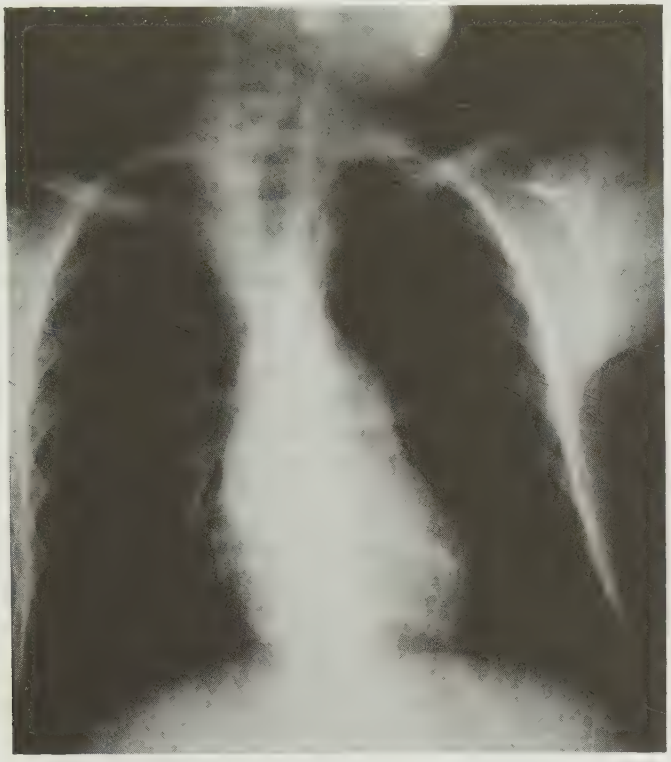

Fig. 81–7. A chest roentgenogram from an 8-year-old boy with mild stenosis of the pulmonary valve. The heart size is usually normal. The pulmonary vascular markings are unremarkable. The most distinctive radiographic feature of this disease is poststenotic dilatation of the pulmonary trunk as depicted here. The degree of dilatation is unrelated to the severity of stenosis.

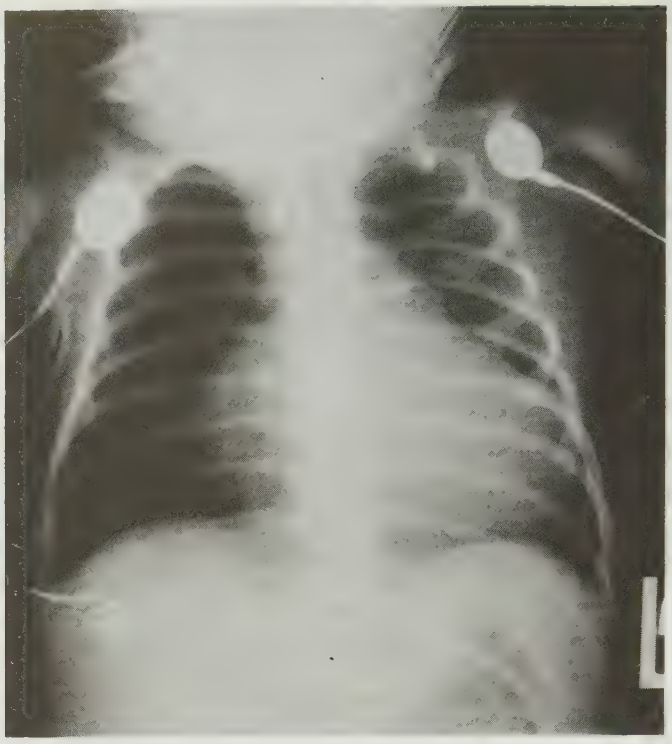

Fig. 81–8. The chest roentgenogram of a newborn with severe pulmonary valve stenosis and intact ventricular septum. There is cardiomegaly with a globular configuration of the heart. The right atrial shadow is prominent and may represent dilatation secondary to tricuspid valve insufficiency. The peripheral pulmonary vascular markings are diminished.

monary valve stenosis, but it has certain limitations.[58,85,100] The diagnosis is based upon the altered hemodynamics affecting the right ventricle and pulmonary artery pressure and their effect upon the motion of the pulmonary valve.[58] With decreased right ventricular compliance, the ventricular end-diastolic pressure exceeds the simultaneous pulmonary artery pressure with a resultant presystolic opening of the pulmonary valve.[53,101] This opening of the valve following atrial contraction corresponds to the exaggerated posterior deflection of the posterior pulmonary valve leaflet (A dip) on the M-mode echocardiogram. In addition, the motion of the pulmonary valve opening is reduced. Children with significant pulmonary valve stenosis may demonstrate right ventricular free wall and ventricular septal hypertrophy as noted on the M-mode echocardiogram.

Unfortunately, the M-mode echocardiographic diagnosis of pulmonary valve stenosis has a number of limitations:[102]

1) The pulmonary valve may be difficult to record, preventing visualization of the diastolic motion pattern.
2. The technique does not permit direct visualization of the stenotic valve, but rather provides indirect diagnostic information based on the effects of abnormal presystolic pressure gradient on pulmonary valve motion.
3. The exaggerated A dip in valve stenosis is not specific and may occur in any condition in which right ventricular end-diastolic pressure exceeds simultaneous pulmonary artery pressure, e.g., Uhl's anomaly.
4. M-mode echocardiography is not generally useful in patients with mild pulmonary valve stenosis, since the hemodynamic abnormalities are not reflected on the pulmonary valve echogram.[103]

For all of these reasons, M-mode echocardiography has very limited diagnostic capabilities in children with pulmonary valve stenosis.

Two-Dimensional Echocardiogram. Two-dimensional echocardiography has become the most widely used noninvasive imaging technique for the evaluation of children with congenital heart disease. By enlarging the area to be investigated and displaying the echocardiogram in an appropriate spatially oriented format, the two-dimensional echocardiogram allows direct visualization of the abnormal pulmonary valve leaflets and the structural consequences of the abnormal flow upon other cardiac structures. Weyman and colleagues reported several important differences in the appearance and motion pattern of the pulmonary leaflets in patients with pulmonary valve stenosis compared to normal individuals:[102]

1) During systole, the leaflets do not lie parallel to the margin of the pulmonary artery, but rather curve inward toward the midportion of the pulmonary trunk. This reflects doming of the pulmonary valve and narrowing of the orifice (Fig. 81–9).
2) The proximal portion of the leaflet echogram moves through a wide arc while the distal tips remain relatively close to-

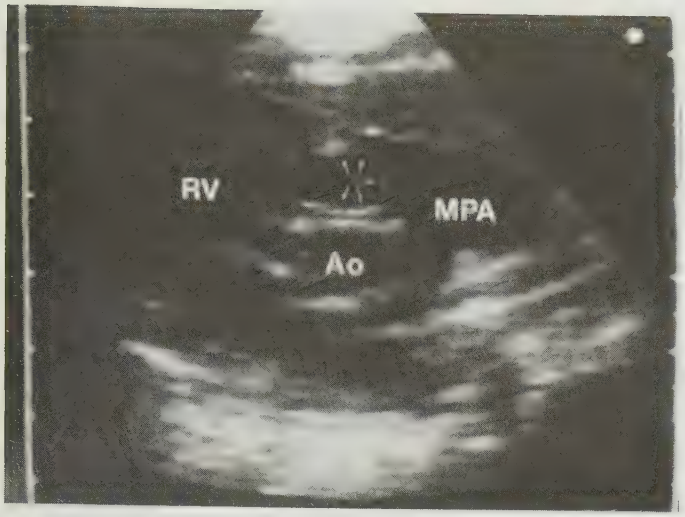

Fig. 81–9. A two-dimensional echocardiogram in an infant with moderate pulmonary valve stenosis. A parasternal right ventricular outflow tract view demonstrates systolic doming of the pulmonary valve leaflets, as outlined by the arrows. The right ventricle (RV), main pulmonary artery (MPA), and aorta (Ao) are also seen.

gether, resulting in an increasingly obtuse angle between the leaflet echoes.

3) Although the pulmonary valve echoes are indistinguishable from normals during most of diastole, the leaflets frequently move to a fully open or domed position following atrial systole in patients with pulmonary valve stenosis.

The actual visualization of the thickened pulmonary leaflets, pulmonary valve annulus, dilated pulmonary trunk, hypertrophic right ventricle, and other associated congenital heart defects are possible with two-dimensional echocardiography. Although the advantages of two-dimensional echocardiography over M-mode echocardiography are apparent, definitive diagnosis of pulmonary valve stenosis by imaging alone is difficult. In Weyman's series, only 64% of patients undergoing two-dimensional echocardiography had adequate visualization of both the anterior and posterior leaflets.[102] Gutgesell and co-workers demonstrated the difficulty in prospectively diagnosing pulmonary valve stenosis by two-dimensional echocardiography alone.[104] The sensitivity of two-dimensional echocardiography was only 76%, misdiagnosing six patients with gradients ranging from 28 to 70 mm Hg. There were also four false-positive diagnoses with a specificity of 97%. As a matter of fact, out of the six most common congenital heart defects, pulmonary valve stenosis was the most difficult to predict with accuracy by two-dimensional echocardiography. In addition to the standard left parasternal short-axis and long-axis views to evaluate the pulmonary valve, the subcostal elongated right oblique view has improved imaging of the right ventricular outflow tract, while the suprasternal notch technique has allowed greater visualization of the pulmonary arteries.[105,106]

Doppler Echocardiogram. It has become quite apparent that with the addition of pulsed and continuous-wave Doppler echocardiography, the detection and prediction of severity of pulmonary valve stenosis have significantly improved.[91,94–96,99,107–109] The Doppler sample volume is moved across the pulmonary valve until the maximal frequency shift, determined by the audible signal, is obtained. Sampling is performed with either an imaging or a nonimaging continuous wave probe from both the high left parasternal surface and subcostal plane, taking care to minimize the angle of incidence between the Doppler signal and the main axis of the pulmonary trunk. The recorded peak flow velocity on spectral display is converted to estimated pressure gradient utilizing the modified Bernoulli equation: $PG = 4V^2$, where PG = instantaneous pressure gradient in millimeters of mercury, and V = peak Doppler velocity in meters per second.[94] Published data have demonstrated that the Doppler-estimated transvalvular gradient in patients with pulmonary valve stenosis correlated well with that obtained from strain-gauge manometry during cardiac catheterization.[88,91,99]

There are important considerations to remember in using Doppler echocardiography to estimate the severity of pulmonary valve stenosis. Doppler velocities represent an instantaneous pressure relationship, whereas recordings obtained at cardiac catheterization are peak-to-peak systolic gradients and may not be directly comparable. The instantaneous gradient is normally greatest in early systole, well before the nonsynchronous peak-to-peak gradient. However, this is less of a practical problem with pulmonary stenosis than with aortic stenosis. Since aortic systolic and pulse pressures are greater in amplitude than those found in the pulmonary artery, the difference between maximal instantaneous and peak-to-peak pressure gradients is less evident in pulmonary valve stenosis than in aortic valve stenosis. For the Doppler estimate to be accurate, a jet must be formed, and this may not occur with small orifices, a factor that causes underestimation of high gradients.[110,111] It is extremely important for the patient to be in a similar hemodynamic state during the echocardiogram and at the time of cardiac catheterization if comparable estimates of severity are to be obtained. In the younger child or infant, sedation prior to the echocardiogram is frequently advised.

New Imaging Techniques. The color-coded, two-dimensional Doppler echocardiogram is able to demonstrate blood flow imaging with simultaneous morphologic imaging. By convention, flow directed away from the transducer is coded as various shades of blue, depending on the velocity, while flow toward the transducer is coded with various shades of red. Extremely turbulent and high-velocity flow patterns, as seen in valvular stenotic lesions, demonstrate a blend of colors, giving rise to green or white. Color flow mapping has nicely demonstrated the abnormal "jet" flow pattern in patients with pulmonary valve stenosis (Fig. 81–10).[112,113] Valdes-Cruz and colleagues suggested a potential error in the estimation of peak instantaneous gradients in the clinical setting using only conventional Doppler echocardiography without color flow mapping to define the spatial orientation and width of stenotic jets.[97,98] This new technique certainly demonstrates promise in improving the accuracy in the detection and prediction of severity in pulmonary valve stenosis.

Contrast echocardiography using the intravenous injection of agitated normal saline solution has also been used in the diagnosis of various congenital heart defects.[114] Its usefulness in the detection of pulmonary valve stenosis is limited, but this technique is very useful to demonstrate right-to-left atrial shunting associated with the obstructive lesion. Color flow mapping may potentially alleviate the need for contrast echocardiography.

X-ray-computed tomography (CT) has been used widely for examination of many organ systems. More recently, with gating

Fig. 81–10. A color-coded two-dimensional Doppler echocardiogram in a child with moderate stenosis of the pulmonary valve. A parasternal right ventricular outflow tract view is performed with imaging of the distal outflow tract, pulmonary valve, and main pulmonary artery. Normal, laminar flow in the right ventricular outlet proximal to the pulmonary valve is color-coded as blue, since the flow is directed away from the transducer. However, spectral dispersion occurs at the stenotic pulmonary valve with turbulent flow transmitted into a dilated pulmonary trunk. This abnormal turbulent flow is color-coded as green with shades of yellow and white. In addition, shades of orange and red are seen in the proximal and lateral pulmonary trunk, representing "aliasing."

of the electrocardiogram, cardiac CT was used to asssess the morphology of various congenital heart defects.[115] Although its use in the diagnosis of pulmonary valve stenosis has been limited, the technique may offer advantages in the quantitative assessment of pulmonary arteries.

Magnetic resonance imaging (MRI) has recently been shown to provide excellent tomographic images of congenital heart defects.[116–119] Jacobstein and associates compared electrocardiogram-gated MRI with two-dimensional echocardiography in evaluating children with congenital heart disease.[120] In general, two-dimensional echocardiography was superior in the evaluation of intracardiac defects and valvular abnormalities, but MRI provided very useful information in the evaluation of aortic arch anomalies and palliative systemic to pulmonary artery shunts. It is also possible that magnetic resonance spectroscopy may be used to evaluate the myocardial energy demands using cardiac phosphorus as a substrate.[121] This may provide a means to evaluate the metabolic cost of specific structural cardiac defects, particularly those affecting ventricular performance, such as pulmonary valve stenosis. Magnetic resonance spectroscopy and positron emission tomography, which are still in their "infancy" stage in the evaluation of children with congenital heart disease, are discussed elsewhere in this text. They may provide the pediatric cardiologist with a new powerful set of tools to be used in the evaluation of children and young adults born with pulmonary stenosis.

Cardiac Catheterization

The role of cardiac catheterization and angiography in the diagnosis and treatment of pulmonary valve stenosis has changed dramatically over the past five years. In the past, hemodynamic and angiographic information was required to select those patients requiring surgical valvotomy and to aid the surgeon in more precise anatomic and physiologic detail. However, since balloon pulmonary valvuloplasty has become the treatment of choice in patients with significant pulmonary valve stenosis, the indications for cardiac catheterization have changed. It is also true that with the use of two-dimensional and Doppler echocardiography providing the diagnosis and determining of the severity of obstruction, the indications for diagnostic cardiac catheterization have been significantly reduced. It should be emphasized that the pediatric cardiologist should use all available information, such as clinical exam, electrocardiogram, chest roentgenogram, two-dimensional or Doppler echocardiogram, and possibly color flow mapping, in an attempt to determine who should undergo catheterization.

Hemodynamics

In patients with pulmonary valve stenosis and intact ventricular septum, the oximetry data depends upon the severity of obstruction and the association of intracardiac or extracardiac shunts, that is, atrial septal defect and patent ductus arteriosus. In mild-to-moderate stenosis with small atrial communication, the oxygen saturations are usually normal. A small amount of bidirectional atrial shunting may be present undetected by oximetry but demonstrated by contrast echocardiography, color-flow Doppler mapping, or indicator dye dilution technique. When the valve stenosis is severe and there is an atrial communication, there is frequently right-to-left shunting with a resultant lower oxygen saturation in the left atrium, left ventricle, and systemic artery than the saturation found in the pulmonary vein. If there is a large atrial septal defect without severe stenosis, there will usually be evidence of left-to-right shunting as measured by oximetry. When a significant patent ductus arteriosus is present, left-to-right shunting into the pulmonary artery is found with increased oxygen saturations compared to those found in the right ventricle.

The most important hemodynamic parameters obtained during cardiac catheterization are the measurements of right ventricular pressure in comparison to systemic arterial pressure and the gradient across the site of obstruction. Carefully performed catheter withdrawal with an end-hole catheter from the pulmonary artery wedge position to the right ventricle will reveal both the site and degree of obstruction. A peak right ventricular systolic pressure less than 35 mm Hg and a systolic gradient across the valve less than 10 mm Hg are considered within normal limits.[122]

The right ventricle generates energy to pump blood through the pulmonary circulation that may be expressed as kinetic energy (velocity) or as potential energy (pressure). Several authors quantitated the relationship between the severity of obstruction and the pressure drop across the valve, but it was Gorlin and Gorlin who expressed this as a pulmonary valve area.[123] Later, several investigators observed the presence of a systolic depression of the main pulmonary artery pressure recording compared to the distal pulmonary artery systolic pressure in patients with significant pulmonary valve stenosis.[124–126] Muster and colleagues emphasize two reasons for the unusual pressure patterns found in patients with pulmonary valve stenosis: 1) increased blood velocity in the main pulmonary artery and 2) architecture of the main pulmonary artery and the right and left branches.[127] As blood accelerates through the stenotic pulmonary valve, more of the total energy is expressed as kinetic energy, a process that results in a drop in pressure, the so-called Bernoulli effect. In addition to the Bernoulli effect (con-

vective acceleration), there are two additional causes for pressure loss: 1) local acceleration secondary to the change in blood velocity over time and 2) frictional losses. However, several studies indicate that it is the Bernoulli effect that predominates in the fall of pressure.[128–130] A negative systolic pressure, owing to a Venturi effect, may also be recorded in patients with severe pulmonary valve stenosis.

The reported average peak systolic velocity in the main pulmonary artery of normal subjects is 57 to 83 cm/s.[131–133] Therefore a threefold to sevenfold increase in peak systolic velocity across the thickened pulmonary valve (200 to 500 cm/s) occurs with an approximate 20 to 100 mm Hg fall in pressure across the valve secondary to the conversion of pressure into kinetic energy (K.E. = $\frac{1}{2}$ pV^2, where K.E. = kinetic energy, p = density of blood, and V = velocity).

Anatomically, the origin of the right pulmonary artery is closer to the pulmonary orifice than the left pulmonary artery. Being nearer to the "dome" of the pulmonary valve, the driving pressure for the flow into the right pulmonary artery is that same pressure in the proximal main pulmonary artery before the jet formed in the thickened valve breaks up. Therefore the pressure recorded in the right pulmonary artery is similar in contour and amplitude to that in the proximal main pulmonary artery. As the jet dissipates in the distal main pulmonary artery and velocity decreases, the kinetic energy component of the total energy decreases and the pressure component increases; the result is a greater mean and peak systolic pressure in the left pulmonary artery.[127] These observations indicate the important role of anatomy of the central pulmonary arteries in regional vascular pressure development and support Chen and colleagues' observation of unequal distribution of pulmonary blood flow in patients with pulmonary valve stenosis, preferentially to the left lung.[134]

As the catheter is withdrawn through the stenotic valve, an abrupt change in the pressure tracing from the low pulmonary arterial pressure to the high-pressure right ventricle is seen. As the stenosis is more severe, the shape of the right ventricular pressure curve becomes more triangular, with a slow rise and descent.[124] In some cases of combined pulmonary valve and infundibular stenosis, two pressure gradients may be found with a characteristic infundibular pressure pulse pattern in severe cases.[125] Because of the high systolic velocity across the narrowed infundibulum, the pressure is decreased owing to the Bernoulli effect. During early systole, both main ventricular and infundibular pressure tracings show a similar initial rise. As blood velocity increases in the outflow tract, the pressure falls there. However, the pressure remains high throughout systole in the main body of the right ventricle. During the remaining portion of systole, the contraction of the hypertrophic infundibular muscle causes a decrease in effective orifice size with subsequent distal increase in velocity and fall in pressure.

The right ventricular end-diastolic pressure may be normal or elevated in patients with severe pulmonary valve stenosis. The right atrial pressure curve usually shows tall A waves in severe obstruction, while in mild-to-moderate stenosis the A wave is frequently normal. A prominent V wave may be present in patients with significant obstruction and secondary tricuspid valve insufficiency. Vogelpoel noted a slow rate of the Y descent with a shallow or absent Y trough in patients with severe infundibular and valvar obstruction, while the Y descent and trough are normal in individuals with mild stenosis.[135]

The normal pulmonary valve area is approximately 2.0 cm^2/m^2 of body surface area. In mild-to-moderate pulmonary valve stenosis, the valve area may range from 1.0 to 2.0 cm^2/m^2. In severe stenosis, the valve area may be calculated to be as low as 0.25 cm^2/m^2 but usually less than 1.0 cm^2/m^2. The presence of associated infundibular stenosis invalidates Gorlin and Gorlin's formula for the calculation of valve area.[42] Assessment of severity of pulmonary valve stenosis requires knowledge of both the pressure gradient and the flow across the valve. A large pressure gradient may be seen in a patient with mild stenosis when the pulmonary flow is high. Conversely, a small gradient may be present in a patient with severe stenosis if the pulmonary flow is low. Hare and co-workers recently demonstrated a simplified formula for the calculation of pulmonary valve area in patients with pulmonary valve stenosis. The simplified formula correlates well with the Gorlin formula.[136]

$$\text{Gorlin formula: PVA } (cm^2) = \frac{CO/HR \times SEP}{C_1 \times C_2 \sqrt{RV - PA}}$$

$$\text{Simplified formula: PVA } (cm^2) = \frac{CO}{\sqrt{RV - PA}}$$

where PVA = pulmonary valve area; CO = cardiac output in milliliters per minute in the Gorlin formula and liters per minute in the simplified formula; HR = heart rate in beats per minute; SEP = systolic ejection period in seconds per beat; C_1 = discharge coefficient with an arbitrary value of 1.0 for the pulmonary valve; C_2 = 44.5 cm/s^2, which is equal to the square root of twice the gravity acceleration; and RV − PA = mean pressure gradient (mm Hg) across the pulmonary valve. The pulmonary valve area is indexed by dividing the calculated valve area from either formula by the body surface area (in square meters).

Muster and co-workers questioned the validity of calculating the pulmonary valve area because blood accelerates across the stenotic valve and the proximal pressure before acceleration and the distal pressure before deceleration are used in the equation.[127] In assessing the severity by using the peak-to-peak systolic pressure difference across the valve, one must question the validity when the Bernoulli effect is so pronounced that the pulmonary arterial curve results in a "valley." A more accurate indicator of severity might be the maximum pressure difference between right ventricle and proximal main pulmonary artery. This would also be more reflective of the Doppler echocardiogram's "instantaneous" peak systolic velocity and calculated gradient.

The measurement of cardiac output during cardiac catheterization is important in evaluating the severity of pulmonary valve stenosis. In our laboratory, the Fick principle is applied using measured oxygen consumption by a "flow-through" technique. It is interesting to note that the data from the U.S. Joint Natural History Study suggested that the most important correlation between peak transvalvular gradient and possible hemodynamic factors influencing the pressure gradient was the heart rate.[75,76] When the pressure gradient is adjusted for heart rate, the inclusion of cardiac output does not improve the accuracy of prediction of severity.

Cotter and colleagues first demonstrated the usefulness of tem-

porary balloon occlusion of an atrial communication in assessing the severity of pulmonary valve stenosis by increasing right ventricular output with a subsequent increase in gradient across the valve.[137]

Exercise Hemodynamics

Measured resting cardiac output in children with pulmonary valve stenosis is usually normal, even in cases of severe obstruction. Several studies using exercise or the infusion of isoproterenol have demonstrated an increase in systolic gradient across the stenotic valve.[138–142] The increase in the rate of right ventricular contraction with subsequent increase in velocity across the obstruction accounts for the pressure gradient increase.[41] Several studies have measured oxygen consumption, oxygen extraction, heart rate, cardiac output, stroke volume, and right ventricular end-diastolic pressure at rest and during exercise in normal children as well as in patients with pulmonary valve stenosis.[142–146]

A study by Krabill and co-workers noted some important differences in exercise hemodynamics between children and adults with pulmonary valve stenosis.[147] Children with mild-to-moderate stenosis usually demonstrated a normal response to exercise, while adults with a similar degree of obstruction often exhibited some hemodynamic abnormalities. Both children and adults with severe stenosis had an abnormal response to exercise, with some notable differences. The most apparent difference was that adults with severe pulmonary valve stenosis have a disproportionately low cardiac index at rest and during exercise when compared to children with similar severity of disease. These adults also had a lower cardiac rate and right ventricular systolic pressure than children with comparable severity but showed the same percentage change from rest to exercise. Stroke index, an indicator of myocardial systolic function, increased significantly with exercise only in children with mild stenosis. Adults with severe stenosis had a lower stroke index at rest and during exercise than adults and children with mild-to-moderate obstruction, but similar to children with severely stenotic valves. Right ventricular end-diastolic pressure was used as an indicator of myocardial diastolic function. Both children and adults with severe stenosis had elevated end-diastolic pressures at rest and an increase in right ventricular end-diastolic pressure with exercise. This abnormal response suggests altered ventricular compliance. Adults with even moderate stenosis also demonstrated an abnormal increase in right ventricular end-diastolic pressure with exercise. In comparable children, the end-diastolic pressure decreased or remained unchanged during exercise, a normal response.[147] These data support the aggressive treatment of moderate-to-severe pulmonary valve stenosis in children, with the hope of avoiding late cardiac dysfunction.

Several other studies have addressed the issue of abnormal cardiac function at rest and with exercise after surgical valvotomy.[148–150] An important difference in younger patients compared to older patients at the time of surgical repair is the reduction of right ventricular end-diastolic pressure and improvement of stroke index at rest and during exercise in children within one year of the operation. This implies that postoperative resolution of muscular hypertrophy is responsible for the improvement seen in children, while myocardial fibrosis explains the lack of improvement in adults.

Classification of Severity

Before proceeding with angiocardiography, clarification of the manner of grading severity of pulmonary valve stenosis is in order. The calculation of pulmonary valve area has several problems, making it unacceptable as an index of severity. The measurement of transvalvular gradient by Doppler echocardiogram and/or cardiac catheterization and the comparison of right ventricular pressure to systemic arterial pressure appear more suitable for determining severity. In our laboratory, *mild* pulmonary valve stenosis is considered to be present if the systolic gradient across the valve is less than 40 mm Hg (particularly in young children) and/or the right ventricular pressure is less than one half the left ventricular pressure. *Moderate* pulmonary valve stenosis is defined as a gradient greater than 40 mm Hg and/or right ventricular pressure greater than one half but less than the left ventricular pressure. *Severe* stenosis is classified as a transvalvular gradient greater than 80 mm Hg and/or right ventricular pressure equal to or greater than left ventricular pressure. These definitions assume a normal cardiac output under resting conditions. It is therefore imperative to measure the cardiac output, especially if the gradient is to be used for management.

Angiocardiography

The introduction of image intensifiers, high-resolution video recorders and monitors, and video disc recording equipment has greatly facilitated the diagnostic and therapeutic interventional techniques for invasive pediatric cardiologists. The use of biplane cineangiocardiography has proved invaluable in identifying the location and assessing the severity of pulmonary stenosis.

Pulmonary valve stenosis is best demonstrated by right ventriculography performed in the standard anteroposterior and lateral projections (Fig. 81–11A, B). To facilitate imaging the leaflets, the anteroposterior camera is rotated approximately 40° to 45° cephalad. Although the pulmonary valve leaflets are seen quite well in the lateral projection, the angled anteroposterior view also allows more detailed imaging of the main pulmonary artery as well as both right and left branches. The stenotic valve leaflets are usually mildly thickened, smooth, and dome in systole. Fused leaflets curl toward the apex of the dome in systole, and a jet of contrast material is seen passing across the valve. In diastole, the leaflets return to a normal position. Although the pulmonary valve annulus is usually normal, in cases of severe stenosis of the newborn or young infant the annulus may be found to be hypoplastic. The main pulmonary artery frequently has poststenotic dilatation with the jet directed along the anterosuperior margin of the artery, extending into the proximal left pulmonary artery. As was stated earlier in the chapter, the degree of poststenotic dilatation does not correlate with the severity of obstruction. A right ventriculogram also allows visualization of tricuspid valve insufficiency if it is present.

The right ventricular morphologic abnormalities secondary to the stenotic valve may also be seen from the right ventriculogram. The trabeculae may be prominent and hypertrophic with a cavity that is usually normal sized, but they may be hypoplastic or even dilated if there is congestive heart failure. The infundibulum may be hypercontractile and hypertrophic, although not displaced. In the lateral projection, the thickened ventricular septum may encroach on the left ventricular outflow tract. The levophase of the right ventriculogram may be of value in assessing pulmonary ve-

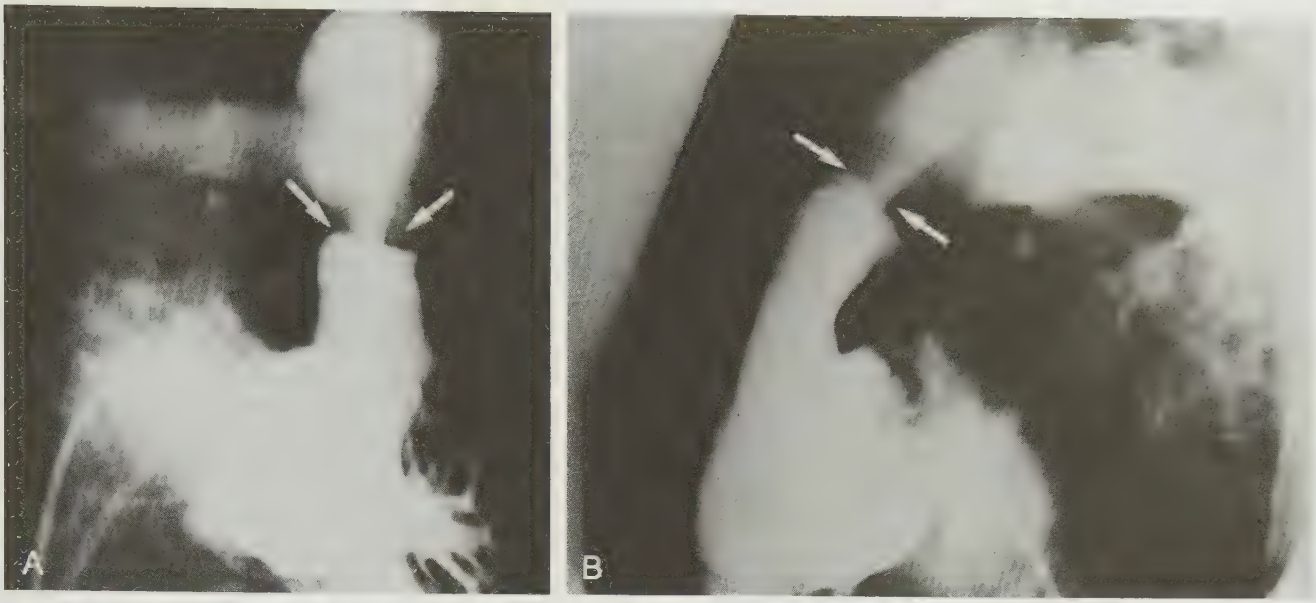

Fig. 81–11. A right ventriculogram in a patient with typical features of moderate pulmonary valve stenosis. (A) Anteroposterior view demonstrating systolic doming of the stenotic leaflets with a "jet" of contrast material noted (see arrows). The infundibulum is widely patent, and the main pulmonary artery is dilated. (B) The lateral projection is also useful in viewing the systolic "jet" that passes through the thickened leaflets as depicted by the arrows.

nous return, presence of an atrial or ventricular septal defect, left ventricular contractility, and presence of a patent ductus arteriosus. However, if the presence of an associated defect causing significant left-to-right shunting is suggested by oximetry, appropriate selective angiograms should be performed. Quantitative right ventricular angiographic measurements in patients with pulmonary valve stenosis and intact ventricular septum have shown that the right and left ventricular functions are usually normal.[151]

Koretzky and associates,[32] and later Jeffrey and associates,[33] characterized the anatomic and angiocardiographic appearance of patients with dysplastic pulmonary valves that distinguish them from the more typical pulmonary valve stenosis. Although the leaflets are not fused, they are extremely thickened with restrictive mobility. The angiogram demonstrates irregular and excessively thickened leaflets that remain deformed and unchanged during the cardiac cycle. The sinuses are narrowed and distorted. One finds that the annulus and the proximal main pulmonary artery are frequently hypoplastic. Systolic doming and poststenotic dilatation are infrequently seen. A report by Schneeweiss and colleagues refuted some of these angiocardiographic criteria for dysplastic pulmonary valve stenosis.[152] In that study, 75% of the patients had poststenotic dilatation, while 33% had a systolic jet. The consistent features found by Schneeweiss and colleagues appeared to be excessive thickening of the valve leaflets (particularly at their edges), a thin base, and little movement of the valve during the cardiac cycle.

The dysplastic pulmonary valve is found frequently in patients with Noonan's syndrome. The levophase of the right ventriculogram in patients with Noonan's syndrome may also be helpful in demonstrating some of the associated abnormalities of the left ventricle.[153] The left ventricle may show eccentric hypertrophy affecting the septum close to the outflow tract, the superior portion of the anterior wall, and/or the diaphragmatic portion of the ventricle.[154] A combined angiographic appearance of the hypertrophy affecting the left ventricle may produce a "ballerina foot" deformity. Hoeffel and co-workers also described cases with dysplastic pulmonary valves and associated supravalve stenosis.[155] Dysplastic pulmonary valve stenosis has also been reported in leopard syndrome and Watson's syndrome.[156,157]

A syndrome of widespread cardiovascular disease associated with pulmonary valve stenosis was described by Becu and co-workers.[158] They pointed out that a thick, tricuspid, relatively immobile pulmonary valve may be only part of a more widespread cardiovascular disease manifested by myocardial dysplasia and necrosis of one or both ventricles, coronary artery occlusion, and a "higgledy-piggledy" aortic wall histology. Myocardial dysfunction at angiography with a dysplastic pulmonary valve and a small, nondistensible ascending aorta should alert the pediatric cardiologist to this pattern of more diffuse cardiovascular abnormalities.

Differential Diagnosis

The diagnosis of pulmonary valve stenosis with intact ventricular septum is usually correctly made if the physician gives careful attention to the physical exam and appropriate use of noninvasive techniques. Most of the cardiac defects that are considered in the differential diagnosis of pulmonary stenosis are discussed more completely in other chapters of this book. Mild pulmonary stenosis must be differentiated from atrial septal defect, pulmonary artery stenosis, ventricular septal defect, idiopathic dilatation of the pulmonary artery, straight back syndrome, mitral valve prolapse, aortic valve stenosis, and innocent pulmonary flow murmurs. If cyanosis is absent and there is moderate-to-severe pulmonary valve stenosis, the diagnosis of ventricular septal defect with or without associated pulmonary stenosis and moderate aortic stenosis must be entertained. The major congenital heart defects that mimic

severe pulmonary valve stenosis with intact ventricular septum presenting with cyanosis are tetralogy of Fallot and pulmonary valve atresia with intact septum. Ebstein's anomaly of the tricuspid valve may sometimes present a confusing clinical picture. We will also review several systemic disease processes that involve the pulmonary valve that must be considered from a diagnostic standpoint when a patient presents with clinical features of pulmonary stenosis.

Atrial Septal Defect

The moderate-to-large secundum atrial septal defect is unlikely to be confused with pulmonary stenosis; atrial septal defect is characterized by the prominent right ventricular impulse, wide and fixed splitting of S_2, mid-diastolic flow rumble over the tricuspid valve, and increased pulmonary vascular markings on chest roentgenogram. However, small defects may be more difficult to differentiate from pulmonary valve stenosis. The systolic ejection click of valve stenosis may be helpful, but an aneurysm of the atrial septum may cause a systolic click. Frequently, echocardiography is necessary to distinguish between the two abnormalities. Clinical and laboratory features of atrial septal defect are discussed in Chapter 60.

Pulmonary Artery Stenosis

Pulmonary artery stenosis is commonly associated with mild pulmonary valve stenosis, and the physical signs are similar. If there are bilateral stenoses, the widely transmitted systolic ejection murmur to the back and lateral lung fields helps to differentiate this abnormality. The murmurs of pulmonary artery stenosis are also characteristically mid- to late systolic in timing. If there are signs of rubella, a family history of siblings with pulmonary stenosis, or intrahepatic biliary dysgenesis, then the diagnosis of pulmonary artery stenosis should be suspected, since these are frequently associated with pulmonary stenosis.

Ventricular Septal Defect

Some infants with pulmonary valve stenosis have a peculiar, low position of the systolic murmur along the left sternal border that may be confused with ventricular septal defect. This is especially true with small defects of the ventricular septum, since the murmur is often diamond-shaped.[163] Vogelpoel and associates demonstrated that the administration of amyl nitrate decreases the length and intensity of the murmur of ventricular septal defect but accentuates the murmur of pulmonary valve stenosis.[164] Although the murmur accompanying aneurysmal transformation of ventricular septal defect may be confused with infundibular stenosis or acyanotic tetralogy of Fallot, it is usually distinct from pulmonary valve stenosis.[165] Supracristal ventricular septal defects (type I) may be heard at the upper or middle left sternal border and may create a difficulty in differentiation from pulmonary stenosis.

In moderate-to-large ventricular septal defects, the murmur is typically holosystolic and located along the left lower sternal border. There is no ejection click, and the second sound depends upon the pulmonary vascular resistance. However, an aneurysm of the ventricular septum with ventricular septal defect can cause a click. There is frequently a mid-diastolic flow rumble located over the mitral valve area with a ventricular septal defect if the left-to-right shunt is larger than 2:1. The chest roentgenogram shows cardiomegaly with increased pulmonary vascular markings, and the electrocardiogram demonstrates left or combined ventricular hypertrophy with ventricular septal defect. Echocardiography easily distinguishes these two congenital heart defects.

Idiopathic Dilatation of the Pulmonary Artery

Clinically, idiopathic dilatation of the pulmonary artery is quite similar to mild pulmonary valve stenosis, since a pulmonary systolic ejection click, a widely split second heart sound, and radiographic features of dilated main pulmonary trunk are also present in this benign condition. Although a systolic murmur may be present, it is quite soft in comparison to pulmonary valve stenosis. The echocardiogram demonstrates a normal-appearing pulmonary valve with normal Doppler flow and should help in differentiating these two conditions. Cases of idiopathic dilatation of the pulmonary artery that were diagnosed clinically in the era before echocardiography have been reclassified as mild pulmonary valve stenosis on more recent followup with Doppler and two-dimensional echocardiographic evaluation. This may be part of the continuum of mild pulmonary stenosis rather than a discrete entity.

Straight Back Syndrome

This syndrome described by Doty may be confused with mild pulmonary valve stenosis, since both have a pulmonary systolic ejection murmur and split second sound. Usually, there is not a systolic ejection click.[166–169] The presence of an associated pectus excavatum and typical chest radiographic features should alert the physician to this condition. Echocardiography demonstrates normal cardiac anatomy.

Mitral Valve Prolapse

Unusual cases of mitral prolapse may present with a nonejection systolic click and systolic murmur located at the middle and upper left sternal border and may be confused with pulmonary stenosis. The unusual transmission of these auscultatory findings has been attributed to the prolapse of the medial leaflet and to the direction of the mitral regurgitant flow toward the more anteriorly located atrial appendage. Echocardiography is a more precise means to diagnose this entity. Mitral valve prolapse is discussed in greater detail in Chapter 114 of this book.

Aortic Valve Stenosis

In young infants, aortic stenosis is occasionally difficult to distinguish from pulmonary stenosis by physical examination alone. The location of the murmur may actually be heard best along the left rather than the right sternal border. The systolic ejection click may be heard diffusely rather than being confined to the apex. The electrocardiogram in both conditions in infancy frequently shows right ventricular hypertrophy. The echocardiogram distinguishes between these two conditions. Occasionally, combined pulmonary and aortic stenoses are present, and the echocardiogram establishes these diagnoses.[170–172] Aortic stenosis is discussed in greater detail in Chapter 79.

Innocent Murmurs

Although their location may be similar, innocent murmurs are usually shorter in duration, softer in intensity, and unaccompanied by a systolic ejection click. Innocent murmurs frequently are low frequency and vibratory in quality with a normally split second heart sound. Trivial degrees of pulmonary stenosis may be indis-

tinguishable from a functional murmur by auscultation. Greater detail on confident differentiation of the functional murmurs is found in Chapter 109.

Tetralogy of Fallot

Cyanotic patients with severe pulmonary valve stenosis and intact ventricular septum must be distinguished from those with tetralogy of Fallot. Typically, the cyanosis is more intense with tetralogy of Fallot. The systolic ejection murmur frequently ends before the single second heart sound in tetralogy of Fallot. An ejection click is often present in the tetralogy of Fallot patient with a greatly dilated aorta but in general is a clue to valvular pulmonary stenosis. The chest roentgenogram usually demonstrates a normal cardiac size, an uptilted right ventricular apex, a deficient pulmonary artery segment, and decreased pulmonary vascular markings in tetralogy of Fallot. The presence of a right aortic arch should strongly alert the pediatric cardiologist to the possibility of tetralogy of Fallot. The electrocardiogram usually has moderate right ventricular hypertrophy in contrast to the severe right ventricular hypertrophy associated with critical pulmonary valve stenosis. The use of echocardiography has allowed the physician to easily diagnose these two conditions noninvasively and expedite appropriate therapy. Tetralogy of Fallot is discussed more completely in Chapter 63.

Pulmonary Valve Atresia with Intact Ventricular Septum

It is not surprising that pulmonary valve atresia with intact ventricular septum may present with features similar to those of severe pulmonary valve stenosis, i.e., cyanosis and congestive heart failure. The pathophysiology is nearly identical, particularly in newborns with critical obstructive stenosis, tricuspid insufficiency, and right-to-left atrial shunting. Both conditions require patency of the ductus arteriosus for adequate pulmonary blood flow. In infants with a hypoplastic right ventricle, the electrocardiogram may demonstrate predominant left ventricular voltage. Radiographically, there are findings similar to critical pulmonary stenosis in infants with cardiomegaly due to a dilated right atrium, decreased pulmonary vascular markings, and a left aortic arch. The echocardiogram in experienced hands usually distinguishes between these two conditions by demonstrating prograde flow through the severely stenotic pulmonary valve. Accurate noninvasive diagnosis allows the pediatric cardiologist to plan for balloon dilation of the critically stenotic pulmonary valve while expediting the readiness of the operating room for the infant with pulmonary valve atresia and intact septum.

Ebstein's Anomaly of the Tricuspid Valve

Ebstein's anomaly occasionally presents as a cyanotic infant with a systolic murmur of moderate intensity over the middle to lower sternal border associated with an active precordium. Chest roentgenogram reveals massive cardiomegaly and decreased pulmonary vascular markings. The electrocardiogram is quite different from critical pulmonary stenosis in these patients, demonstrating reduced voltage, right bundle branch block, and right atrial enlargement. The echocardiogram demonstrates classic features of an inferiorly displaced septal leaflet and long redundant anterior leaflet of the tricuspid valve. Further discussion of this malformation is found in Chapter 68.

There are a number of other cyanotic congenital heart defects that one has to consider in the differential diagnosis of severe pulmonary valve stenosis with right-to-left atrial shunting. A percentage of these defects may have pulmonary stenosis as an associated feature. However, the expert use of two-dimensional, Doppler, and color flow echocardiography should permit differentiation of all of these conditions and allow for prompt and appropriate therapy.

Systemic Diseases Associated with Pulmonary Stenosis

Myocarditis, glycogen storage disease, and left ventricular obstructive disease have been reported to produce infundibular and valvar pulmonary stenosis.[173–177] Tophaceous deposits have been demonstrated in the pulmonary valve secondary to gout.[178] Gottsegen and colleagues[179] and Catton and colleagues[180] reported that right ventricular or pulmonary valvar myxomata may closely resemble severe isolated pulmonary valve stenosis. Two-dimensional and Doppler echocardiography have been used to diagnose right ventricular outflow obstruction secondary to external compression from an anterior mediastinal tumor.[181,182] Intracardiac goiter has also been implicated as a cause of right ventricular outflow tract obstruction.[183] Neurofibromatosis, or von Recklinghausen's disease, has been reported to cause both infundibular and valvar pulmonary stenosis.[184–186] Pulmonary valve and artery stenosis have been reported in multiple lentigines syndrome, or leopard syndrome.[156,187] Watson described a syndrome of patients with pulmonary stenosis, cafe-au-lait spots, and dull intelligence.[157]

Carcinoid disease of the bowel has been associated with endocardial fibrosis of the right ventricle with infiltration of the pulmonary and tricuspid valves leading to stenosis of variable severity.[188] Symptoms including abdominal pain, diarrhea, weight loss, flushing, and generalized telangiectasia have been attributed to excessive release of serotonin. Carcinoid occurs in older children or adults.

It is worthwhile to reemphasize that Noonan's syndrome is associated with congenital heart disease in 50% of the cases, usually dysplastic pulmonary valve stenosis.[17,29] Hypertrophic cardiomyopathy with or without pulmonary stenosis has been reported in 25% of cases.[189] These patients may present a problem in determining the severity of obstruction from physical exam. The ejection click is usually absent, and the systolic murmur may be of low intensity, despite the severity. An atypical electrocardiogram showing left axis deviation may be found. It is wise to investigate children suspected of having Noonan's syndrome quite thoroughly as well as inquiring about other family members.

Natural History

Most pediatric cardiologists would agree that mild pulmonary valve stenosis has a benign clinical course and requires no therapy. No deaths were reported from a study of 214 patients with mild stenosis in a four- to eight-year followup.[190] In the U.S. Joint Study of the Natural History of Congenital Heart Defects, among 261 patients treated medically, only three with initial gradients of less than 40 mm Hg had gradients of 60 mm Hg or more over a period of four to eight years.[76] The actual mean pulmonary valve gradient in this group of patients was unchanged or decreased over the years of followup. Furthermore, catheterization studies have shown normal cardiac output at rest and during exercise with a completely normal hemodynamic response to exercise in patients with mild pulmonary valve stenosis. One study has actually doc-

umented a decrease in right ventricular systolic pressure and transvalvular gradient with time that might be attributed to an increase in the stenotic pulmonary orifice size as the child grows.[191]

There is controversy regarding the clinical course and prognosis of children with moderate pulmonary valve stenosis.[192,193] In Jonson and associates' study of 21 asymptomatic adult patients with pulmonary valve stenosis, no cardiac symptoms or complications developed over a period of 15 years.[194] Data from most centers as well as the information from the U.S. Joint Study suggest that infants and children with moderate stenosis, especially those with severe obstruction, may develop progressively higher transvalvular gradients.[76,190] A more recent study by Lange and co-workers demonstrated a significant gradient increase of 8.6 mm Hg/yr in a followup over 2 to 12 years in infants and children with an initial systolic gradient of greater than 50 mm Hg. This was quite different from the −0.6 mm Hg/yr gradient decline in patients with an initial pulmonary valve gradient of less than 50 mm Hg.[195] Krabill and associates' exercise data in patients with moderate pulmonary valve stenosis reviewed earlier in this chapter implied reduced systolic and diastolic function of the right ventricle.[147] Although prediction of the clinical course of moderate pulmonary valve stenosis is difficult, newer data seem to support more aggressive therapy in these individuals. This is especially true since balloon pulmonary valvuloplasty with low risk and high efficacy has become available.

In the U.S. Joint Study of 261 patients treated medically, there was no improvement in severe obstruction with gradients in excess of 80 mm Hg.[76] An increase in gradient is possible during periods of rapid growth, i.e., infancy and adolescence. Hemodynamic deterioration can occur by three mechanisms:

1) As the child grows, the orifice of the stenotic pulmonary valve can remain constant. Danilowicz and colleagues found that in 17 of 32 infants with pulmonary stenosis, the pulmonary valve area decreased with age.[196] In older children with pulmonary stenosis, serial cardiac catheterizations have shown that the pulmonary valve area increased proportionally to the increase in body size and cardiac output.[197,198]
2) Right ventricular myocardial function may be impaired by the development of fibrosis or hypertrophy. In the 64 children studied by Moller and co-workers, those with severe pulmonary stenosis had evidence of myocardial dysfunction believed to be a result of myocardial hypertrophy in the majority and myocardial fibrosis in three children.[139] Adults with severe obstruction had a lower cardiac index at rest and during exercise than any other group of adults or children with pulmonary stenosis.[147]
3) Infundibular hypertrophy may develop, causing a secondary site of right ventricular outflow tract obstruction.[196,199]

Although the development of symptoms during the first two years of life is associated with severe obstruction, one should not rely on symptoms being present to establish the severity of disease.[76,200] In the U.S. Joint Study, none of the medically treated children younger than 12 years of age with pulmonary valve gradients greater than 80 mm Hg had symptoms, although the majority had radiographic or electrocardiographic abnormalities.[76] In another series, 33% of patients with right ventricular pressure greater than 120 mm Hg demonstrated symptoms.[190] Serial catheterization data in patients with severe pulmonary valve stenosis are lacking, since the majority of these patients are treated. However, clinical and electrocardiographic data suggest a progression in severity of obstruction. Regardless of the degree of elevated right ventricular pressure, the presence of congestive heart failure is an ominous sign and requires immediate therapy.

Sudden death has been reported in children without apparent relation to unusual strenuous activity.[65,66,201,202] In the current era, sudden death in children is rare, and most deaths occur in newborns with critical pulmonary valve stenosis.[2,45,76,203] Cyanosis is very common in the severe form of this disease in young infants, being present in 50% of those with gradients in excess of 80 mm Hg. The presence of hypoxic spells has been recognized as a grave prognostic sign.[204]

Abbott described two cases of infective endocarditis in 25 autopsies of patients with pulmonary valve stenosis.[205] Abrahams reported a relatively high incidence of endocarditis (3% of their cases).[1] In the U.S. Joint Study, only 2 out of 598 patients with pulmonary stenosis had a history of infective endocarditis.[76] Infective endocarditis seems to constitute a relatively minor risk to individuals with pulmonary valve stenosis and intact septum regardless of medical or surgical treatment. Appropriate antibiotic prophylaxis should be administered before any indicated procedure.[206]

Treatment

Medical

Children with mild pulmonary valve stenosis do not require surgical or balloon valvuloplasty intervention. Cardiac catheterization is unnecessary unless the patient is symptomatic or noninvasive testing suggests more obstruction than is evident from clinical examination. These patients are generally followed as outpatients every one to two years with electrocardiogram and echocardiogram to assess changes in severity. There should be no restriction of physical activity. Infective endocarditis prophylaxis is required for all procedures indicated by the American Heart Association.[206]

The treatment of moderate pulmonary valve stenosis is more controversial. Certainly, if these patients are symptomatic, treatment is required. However, if the patients are asymptomatic, the question of therapy is more uncertain. Before the development of balloon pulmonary valvuloplasty, most pediatric cardiologists hesitated to recommend surgical valvotomy in these asymptomatic patients. Yet most physicians were concerned that the long-term right ventricular hypertrophy might lead to functional impairment of the myocardium later in life. Recent studies tend to substantiate these concerns in adults with pulmonary valve stenosis.[147] Therefore we have been more aggressive in the treatment of patients with moderate or moderate-to-severe obstruction. Recommendations depend upon the individual's size, age, and noninvasive test results. Infants and younger children with Doppler-estimated systolic gradients in excess of 40 mm Hg and/or evidence of right ventricular hypertrophy currently undergo cardiac catheterization for possible balloon pulmonary valvuloplasty at our center. Older children with estimated transvalvular gradients of greater than 50 mm Hg and/or right ventricular hypertrophy undergo catheterization with anticipated balloon valvuloplasty.

Untreated infants and young children with moderate pulmonary valve stenosis may need to be seen twice a year as outpatients to evaluate for progression of the disease. Older children and adults

should be seen on a yearly basis with appropriate tests. Exercise studies may be helpful in older individuals to unmask hemodynamic abnormalities. Appropriate infective endocarditis prophylaxis is recommended. If a physician is restricting physical activity in an untreated child on the basis of moderate pulmonary valve stenosis, then balloon valvuloplasty should be performed.

Asymptomatic patients with severe pulmonary valve stenosis should have hemodynamic and interventional cardiac catheterization performed as a semielective procedure. Symptomatic newborns and infants with severe or critical obstruction require immediate treatment. In infants with evidence of right-sided congestive failure and inadequate pulmonary blood flow, the administration of prostaglandin E_1 (PGE_1) infusion intravenously may be life saving by providing adequate pulmonary blood flow through the patent ductus arteriosus. The dose of PGE_1 ranges from 0.05 to 0.10 μg/kg/min with special care to observe for apnea and attention to the possible need for endotracheal intubation. In addition, furosemide (1 mg/kg/dose) and digoxin (total dose of 40 μg/kg to be divided appropriately) may improve signs of congestive heart failure temporarily. However, the infant should be stabilized as quickly as possible and proceed to the cardiac catheterization laboratory for balloon pulmonary valvuloplasty. We routinely alert the pediatric cardiovascular surgeon to the possibility of surgery in case the balloon dilation is unsuccessful. The infusion of PGE_1 is continued during and after the procedure to ensure adequate pulmonary blood flow. The dosage of the medication is gradually reduced and discontinued while the patient's clinical condition and systemic oxygen saturations are observed. The clinical course and prognosis in these infants are variable depending on their clinical condition before ballooning, the degree of tricuspid valve insufficiency, the amount of residual pulmonary valve insufficiency, and, perhaps most important, the size and function of the right ventricle. Followup clinic visits and studies depend upon the clinical status but usually occur every two to three months during the first year of life and one to two times a year thereafter. Again infective endocarditis prophylaxis is important.

Balloon Pulmonary Valvuloplasty

Percutaneous, transluminal balloon angioplasty has been used in the treatment of adults with stenoses of coronary and peripheral arteries since 1976.[207–210] In 1980, the first successful balloon valvuloplasty for congenital pulmonary valve stenosis was performed on Rumbo, an English bulldog, by Kan.[211] Two years later, Kan and co-workers reported the success of this new procedure in an eight-year-old asymptomatic patient with pulmonary valve stenosis.[212] Later, Lababidi and Wu[213] and Kan and co-workers[214] reported their successes in the application of balloon valvuloplasty in children with moderate-to-severe congenital pulmonary valve stenosis. This was the beginning of an explosion of reports of success using this new technique in children and adults with congenital stenoses of all cardiac valves, conduit valves, pulmonary arteries, and coarctation of the aorta.[215–230] The pediatric interventional cardiac catheterization laboratory had begun and added a stimulating new aspect to the management of congenital heart disease that was comparable to the advent of echocardiography in the 1970s.

The physical properties governing balloon angioplasty depend on transmission of a controlled radial force through a rigid balloon.[231] The characteristics of the stenotic tissue determine the effectiveness of the dilation process. Although Semb and co-workers had relieved pulmonary valve stenosis by pulling a carbon dioxide–filled balloon from the pulmonary artery to the right ventricle, this technique had the inherent dangers of avulsion of the valve leaflets.[232] The hypothesis of using transluminal balloon dilation of the stenotic valve as an alternative to surgery was based on several observations: 1) the surgical success of relieving pulmonary valve stenosis by using inflow occlusion and manual dilation techniques, 2) the ability to construct polyethylene balloons of almost any size in which high pressure can be applied without overdistension of the balloon, and 3) the ability of the right ventricle to adequately function after surgical valvectomy.[233] The initial investigators felt that the mechanism of dilation was rupture of valve tissue.[212,213] Therefore, the balloon diameter was chosen not to exceed the angiographically measured pulmonary valve annulus diameter, and high inflation pressures, up to 120 psi (8 atmospheres), were used. Since the early studies, there have been significant improvements in catheter design, in balloon material, and in the actual technique of performing the valvuloplasty procedure.[234–239] With unoperated, typical pulmonary valve stenosis, it was demonstrated that balloons 20 to 40% larger than the angiographically measured pulmonary valve annulus were both safe and more effective.[235] The predilation average systolic gradient of 65 mm Hg was reduced to a mean valvular gradient of 16 mm Hg, a 74% reduction. The use of oversized balloons allowed less inflation pressure to be applied, usually only 4 to 6 atmospheres. This observation is in accordance with the law of Laplace, which states that force is proportional to diameter times pressure.

The single, oversized balloon technique worked well when the pulmonary valve annulus was less than 20 mm in diameter. However, it became apparent that a double-balloon technique would be necessary for adequate relief of pulmonary valve stenosis in larger individuals.[235–237] In selecting the proper size of the two balloons, the reader is referred to Radtke and colleagues' article,[235] and to the part of this book that covers interventional cardiology (Chapter 130). The double-balloon technique has an advantage of "venting" the right ventricle during peak inflation because of the elliptical geometry. The efficacy was apparent with an average reduction in peak systolic pressure gradient from 104 mm Hg before ballooning to 24 mm Hg after balloon dilation.[237] The technique has also been shown to be quite safe. Several disadvantages of the technique are the additional time of inserting and positioning two balloon catheters, the introduction of a large-diameter catheter into both femoral veins, and the additional help required to inflate and position both balloons at the same time. However, since the largest single-balloon diameter is 25 mm at present, the double-balloon technique is necessary to provide adequate relief of obstruction in patients with a pulmonary valve annulus diameter greater than 20 mm. Recent reports from Switzerland and the Netherlands have described two experimental catheter designs with potential benefits using a trefoil balloon and a triple-lumen balloon, respectively.[238,239] Both designs allow transvalvular prograde flow during balloon inflation and have added cross-sectional area because of their configuration. The future certainly appears bright for improved catheter and balloon design for the pediatric cardiologist.

Studies have described the pulmonary valve morphology after balloon dilation for valve stenosis.[240–242] Balloon pulmonary val-

vuloplasty produced relief of obstruction by commissural splitting in patients with the more common and typical thin, doming valve. Usually, only one commissure was opened. When significant infundibular obstruction accompanied pulmonary valve stenosis, the risk of cusp avulsion was higher.[213,240] When the commissures were poorly formed with extensive valvar fibrosis, cusp tearing was more likely to occur. The pulmonary valve morphology in dysplastic valve disease is important. It should come as no surprise that the results of balloon dilation for dysplastic pulmonary valve stenosis are poor.[214,235,242,243] Despite the use of oversized balloons, no relief of obstruction occurred. As a matter of fact, several patients actually had an increase in transvalvular gradient after attempts to balloon-dilate the dysplastic valves.[243] The causes of valvuloplasty failure in these patients include not only the myxomatous, obstructive valve tissue with unfused commissures, but also a hypoplastic main pulmonary artery despite a near-normal-sized valve annulus. In this group of patients, surgical valvectomy remains the treatment of choice.

The risks of percutaneous transluminal balloon pulmonary valvuloplasty are low. We are not aware of deaths reported during this procedure for isolated pulmonary valve stenosis. During the peak inflation or early deflation portion of the procedure, sinus bradycardia and arrhythmias have been noted. Arrhythmias have consisted of premature ventricular contractions, nonsustained ventricular tachycardia, accelerated junctional rhythm, advanced atrioventricular block, and right bundle branch block. Some physicians administer atropine prior to the balloon inflation to minimize the bradycardia. Henry and associates reported an unusual right ventricular pulsus alternans pattern during acute increase in afterload occurring during balloon pulmonary valvuloplasty. The pattern resolved spontaneously.[244] With the use of double balloons or perhaps the newer trefoil or triple-lumen balloons, the incidence of these side effects may diminish.

With the use of proper-sized balloons, pulmonary valve annulus rupture has not been reported. The incidence of residual mild pulmonary insufficiency after balloon valvuloplasty varied from 13 to 20%.[222,235,241] The use of Doppler echocardiography and color flow mapping may increase the detection of pulmonary insufficiency, but this low percentage compares favorably to the 57 to 70% incidence after surgical valvotomy.[76,245] Infundibular spasm has been reported after percutaneous balloon dilation of the stenotic pulmonary valve and after surgical valvotomy (Fig. 81–12A, B).[213,214,221,235,237,246] Propranolol was successfully used for some patients with acutely reduced right ventricular output. However, the role of beta-blocker therapy for infundibular narrowing after relief of the transvalvular gradient is still uncertain. It appears that the secondary infundibular hypertrophy and narrowing are transient. Fontes and co-workers recently reported complete regression of the right ventricular infundibular hypertrophy approximately ten months after balloon pulmonary valvuloplasty in patients with suprasystemic right ventricular pressure.[247] Another potential complication from balloon valvuloplasty is femoral venous thrombosis or intimal damage of the vessel.

In any patient being considered for pulmonary balloon valvuloplasty, we perform complete echocardiographic studies. Special attention is given to obtain a continuous-wave Doppler pulmonary valve velocity while the patient is resting quietly or sedated. We have also found an accurate correlation of the balloon diameter required and the pulmonary annulus measurement obtained from the parasternal right ventricular outflow view on the two-dimensional echocardiogram (Fig. 81–13).[248] If the annulus measurement is made at the base of cusps during systole and from the middle of the anterior to posterior walls (rather than inside the lumen), then the diameter of the balloon necessary for successful dilation equals the echo-derived measurement (Fig. 81–14). During catheterization, standard right and left heart resting hemodynamics are obtained, including measurement of cardiac output by Fick technique. Slow pullback pressure recordings are obtained by using an end-hole catheter. Next, a selective right ventricular angiocardiogram is performed with the anteroposterior camera cranially angulated at 40° and a straight lateral projection. We then repeat the measurements of the right ventricular pressure and transvalvular gradient after angiograms. Calibration grids are recorded and used to measure the pulmonary valve annulus from the angiogram (Fig. 81–15A, B). Others have used calibrated marker catheters for this purpose. By multiplying this measurement by a factor of 1.3, the annulus diameter obtained by echocardiography is usually equalled. An end-hole catheter is repositioned into the distal left pulmonary artery, an appropriate exchange guidewire is placed through the catheter into the left pulmonary artery, and the catheter is withdrawn. While the technician is flushing the balloon catheter with diluted contrast solution (20%) to avoid air within the balloon, a second percutaneous femoral vein catheter is inserted and placed into the right ventricle for pressure measurement during the balloon dilation procedure. The balloon catheter is then advanced over the exchange guidewire, with care taken that the wire remains in the distal left pulmonary artery. Pepine and colleagues observed that the guidewire remaining in the pulmonary artery lessened the risk of pulmonary artery perforation during either catheter advancement or balloon inflation.[249] After the balloon catheter is positioned where the midportion of the balloon coincides with the stenotic pulmonary valve, the balloon is inflated rapidly under fluoroscopy using a hand-held manometer until the "hourglass" waist from the stenotic valve disappears or until the maximum recommended atmospheric pressure is reached (Fig. 81–16A, B). Rapid deflation is performed (total inflation–deflation time less than 7 seconds), and the entire procedure is repeated with repositioning of the balloon catheter as needed or replacement of the catheter with a larger balloon if indicated. Right ventricular and systemic arterial pressures are constantly monitored throughout the procedure. After balloon valvuloplasty has been completed, the cardiac output and transvalvular pressure gradient measurements are repeated (Figs. 81–17 and 81–18). Finally, a repeat right ventricular angiogram is performed. We then routinely perform a postvalvuloplasty two-dimensional and Doppler echocardiogram while in the catheterization laboratory or soon after the patient has been transferred for recovery (Fig. 81–19A, B). A reevaluation of the patient's estimated transvalvular gradient and assessment for pulmonary insufficiency is made. We also repeat an electrocardiogram to assess for any acute changes after the valvuloplasty procedure. Usually, the patient is ready to be discharged on the morning after the procedure. Although we do not routinely have surgical "standby" during the balloon dilation, a precatheterization type and crossmatch for possible blood transfusion has been obtained. In the case of newborns or young infants with critical pulmonary valve stenosis, we do alert our surgeons before the case is started. In addition, we agree that graduated sequential balloon dilation as described by Ali Khan

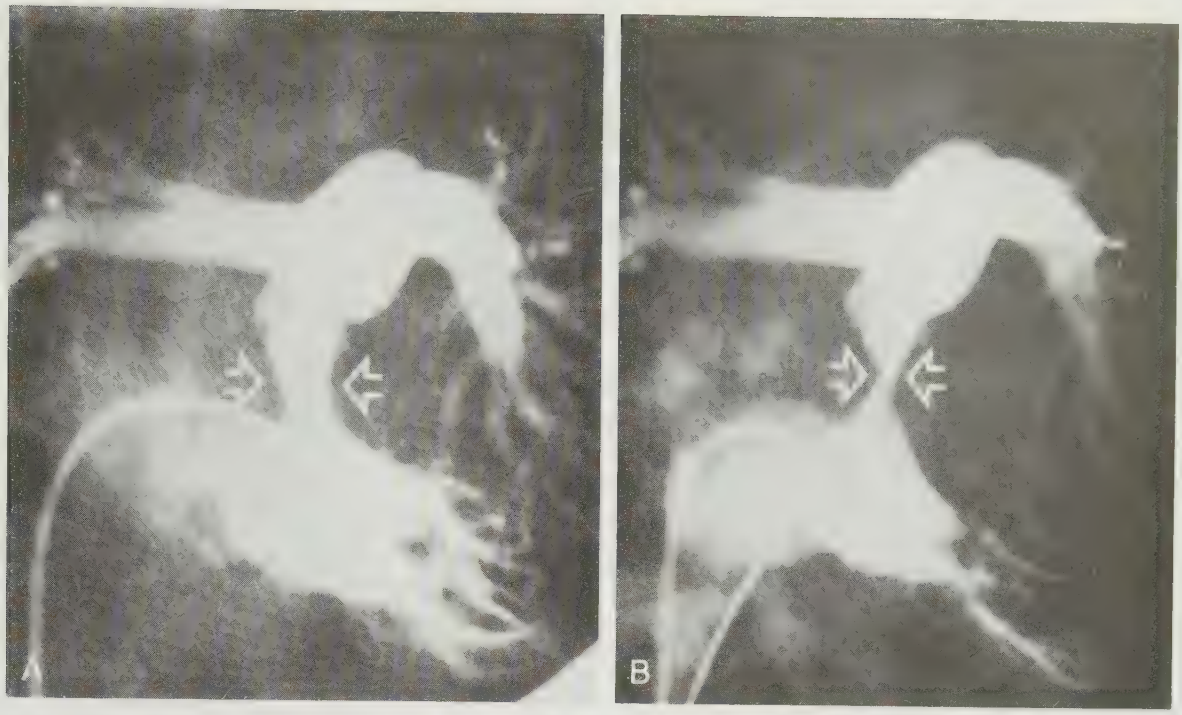

Fig. 81–12. A right ventriculogram in an infant undergoing balloon pulmonary valvuloplasty for severe pulmonary valve stenosis with suprasystemic right ventricular systolic pressure. (A) Preballooning: An anteroposterior projection with 40° cranial angulation allowed visualization of the mildly hypertrophic and narrowed infundibulum (arrows). The angiocardiogram also demonstrated systolic doming of the pulmonary valve with poststenotic dilatation. (B) Postballooning: A repeat angiocardiogram demonstrates severe infundibular narrowing that has significantly increased since the valvuloplasty procedure (arrows). This secondary obstruction was transient with evidence of improvement over several weeks. No treatment with beta-blocker medication was necessary.

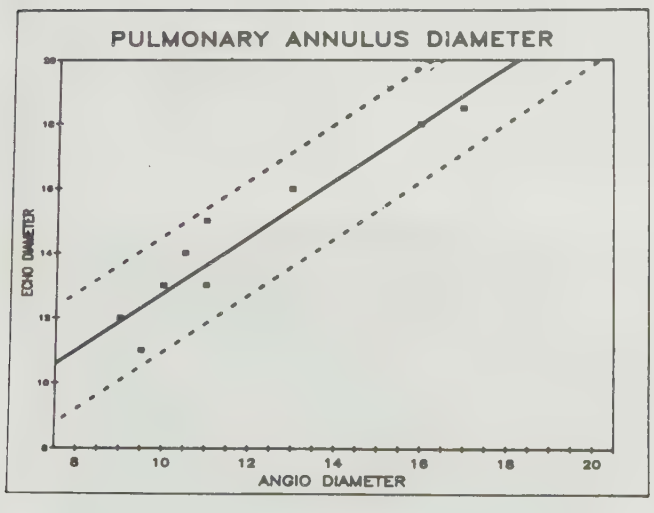

Fig. 81–13. A graph from our laboratory demonstrating the relationship between pulmonary annulus diameter measured from two-dimensional echocardiography and the diameter measured by angiography. As a rule, the two-dimensional echocardiographic measurement is 1.2 to 1.3 times the angiographic measurement. Since a balloon diameter 1.2 to 1.3 times the annulus measured from angiography is frequently chosen, the two-dimensional echo appears to be an accurate method of predicting the proper balloon size for pulmonary valvuloplasty.

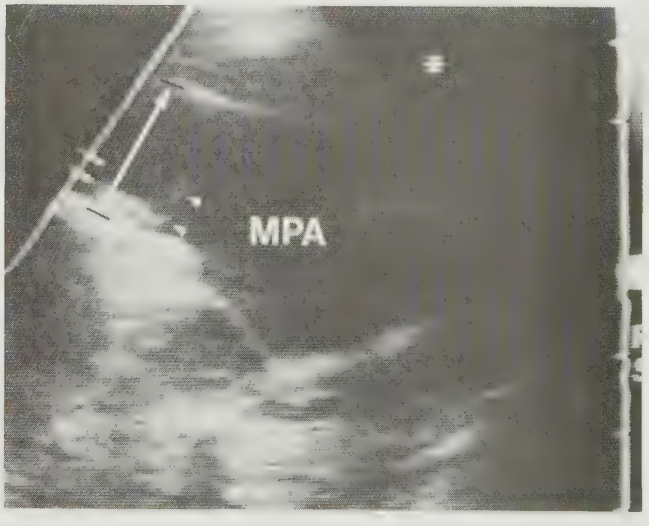

Fig. 81–14. A two-dimensional echocardiogram obtained from the parasternal right ventricular outflow tract view. The pulmonary valve annulus is measured at the base of the leaflets from the middle of the anterior and posterior walls, as depicted by the long arrow between the black markers. This annular diameter is predictive of the necessary balloon size for successful valvuloplasty. The pulmonary valve leaflets dome in systole (the two small arrowheads), and the main pulmonary artery (MPA) is dilated.

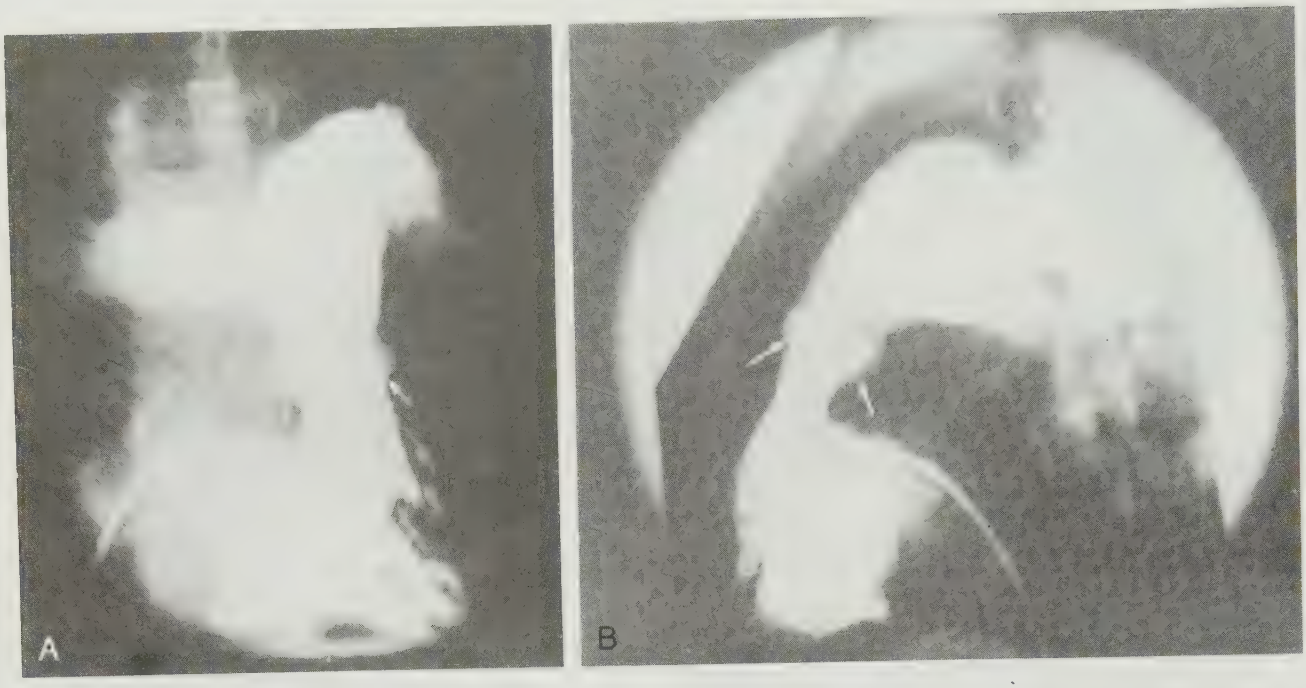

Fig. 81–15. A right ventriculogram used for measurement of the pulmonary valve annulus diameter. (A) The anteroposterior view with the base of the pulmonary leaflets depicted by arrows. The distance between the two arrows is the angiographic annular diameter. This value (in millimeters) times 1.2 to 1.3 usually equals the proper balloon size for successful valvuloplasty. (B) The lateral view also is helpful in measuring the pulmonary valve annulus (distance between the arrows).

and co-workers is frequently necessary in the infants with critical obstruction (Fig. 81–20a, b, c, d).[250]

Long-term followup of patients who have had balloon pulmonary valvuloplasty is still limited. Several authors have demonstrated persistent relief of right ventricular hypertension for up to three years.[213,214,220,235,235] In addition, improvement of both right ventricular hypertrophy on electrocardiogram and a lower-intensity systolic murmur are common. The benefits of the procedure are many. The procedure can be performed during hemodynamic cardiac catheterization and eliminates the need for general anesthesia and open heart surgery. Valvuloplasty eliminates the exposure to blood products. It reduces the hospitalization period from 7 to 10 days to less than 48 hours in most instances with a reduction in cost. It can also be performed in children with other major medical illness that might make them poor anesthetic or operative risks. There is the additional benefit of no surgical scar, cosmetic or psychologic, and the procedure can be repeated if necessary.

Although the long-term results are still unknown, the current data strongly support the statement that percutaneous transluminal balloon valvuloplasty is the treatment of choice for patients with

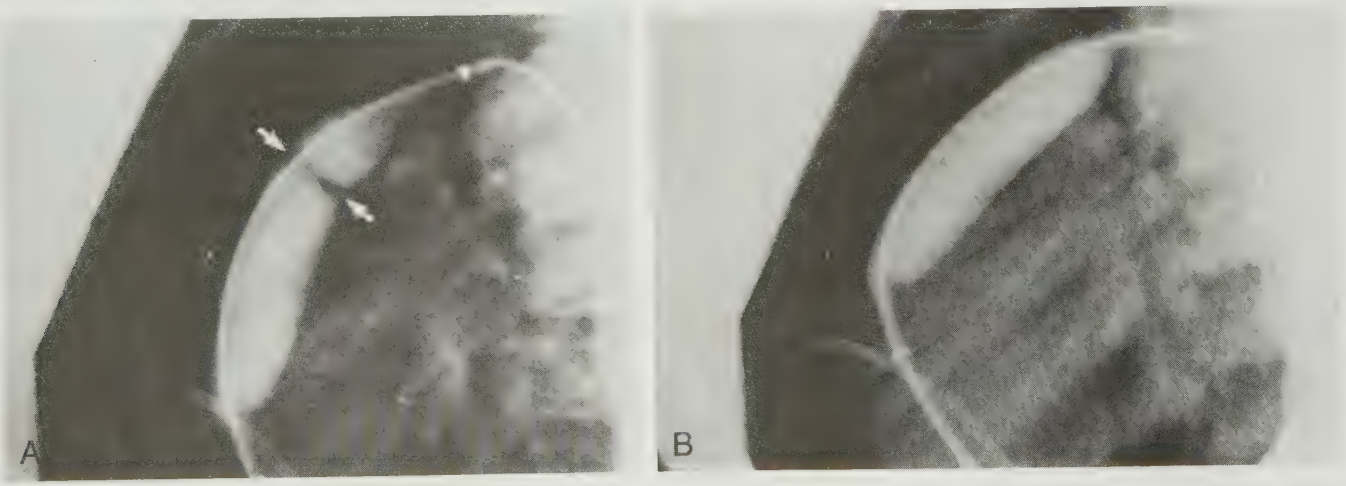

Fig. 81–16. Proper positioning of the balloon catheter for pulmonary valvuloplasty using the lateral view under fluoroscopy. (A) A guidewire is passing through the catheter from the right ventricular outflow tract into the left pulmonary artery. The balloon is inflated with diluted contrast (20%) until a "waist" is seen that corresponds to the stenotic valve leaflets (arrows). Proper positioning of the catheter is performed in an attempt to maintain the waist at the midportion of the balloon. In this case, the waist is toward the distal one third of the balloon. (B) The balloon has been repositioned more distally and completely inflated by using a handheld manometer. Note that the hourglass waist has completely disappeared.

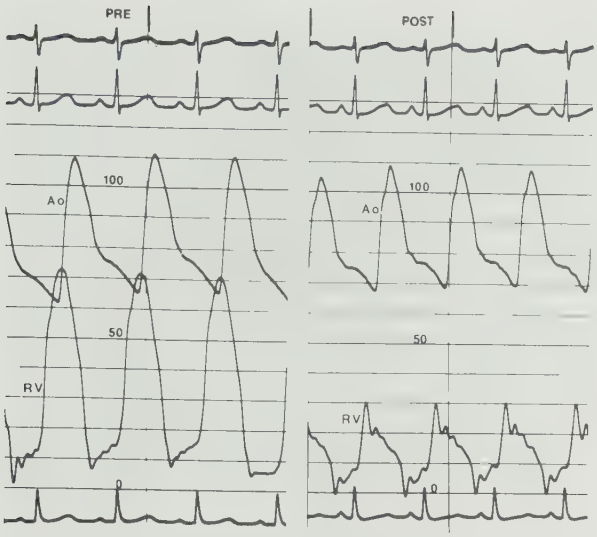

Fig. 81–17. Pressure recordings obtained at cardiac catheterization before and after balloon valvuloplasty for moderate pulmonary valve stenosis. In the left panel, the right ventricular (RV) systolic pressure is somewhat greater than 70 mm Hg before balloon valvuloplasty (PRE). Note the triangular appearance of the RV pressure curve, which indicates significant stenosis. After valvuloplasty (POST), the RV systolic pressure decreased to 30 mm Hg with a completely normal pressure curve. Aortic (Ao) pressure remained unchanged during the procedure.

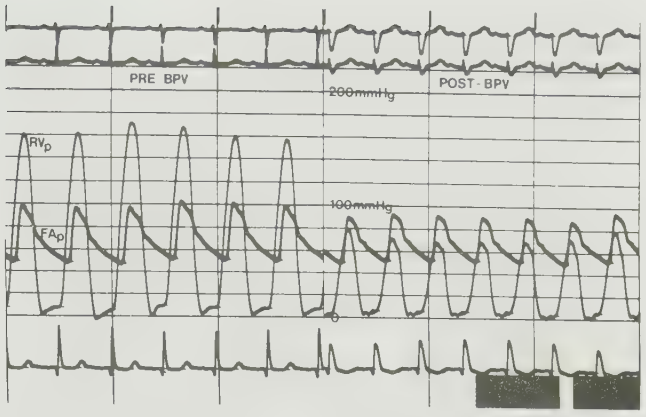

Fig. 81–18. Cardiac catheterization data obtained during balloon pulmonary valvuloplasty for severe stenosis in a five-month-old infant. Before valvuloplasty (PRE-BPV), the right ventricular systolic pressure (RVp) is approximately 170 mm Hg as compared to the femoral artery systolic pressure (FAp) of 100 mm Hg. After ballooning (POST-BPV), the RVp decreased to 70 mm Hg while the FAp diminished slightly to 95 mm Hg. The triangular RVp curve remained after balloon valvuloplasty and indicated some persistent obstruction. This infant had angiographic evidence of infundibular spasm that later resolved spontaneously. Note that the patient also had transient bundle branch block on the electrocardiogram.

nondysplastic pulmonic valve stenosis if the severity warrants intervention. Surgical valvotomy or valvectomy should be reserved for those patients in whom balloon valvuloplasty is unsuccessful or for those with dysplasia of the pulmonary valve.

Surgery

Sellors[251] and Brock[252] reported the first successful attempts at operative relief of pulmonary valve stenosis with intact ventricular septum. An initial experience of poor relief of obstruction from this technique led other surgeons to attempt valvotomy under hypothermia and direct visualization through the pulmonary artery.[253,254] Larger numbers of patients have now been treated by using cardiopulmonary bypass with transarterial pulmonary valvotomy.

Varco introduced the technique of inflow occlusion with "blind" pulmonary valvotomy in 1951.[255] Later, Mistrot and colleagues reported the successful use of inflow occlusion for isolated pulmonary valve stenosis in 110 patients ranging from two days to 36 years old.[256] Sade and associates demonstrated that inflow occlusion with transarterial valvotomy was as successful, as safe,

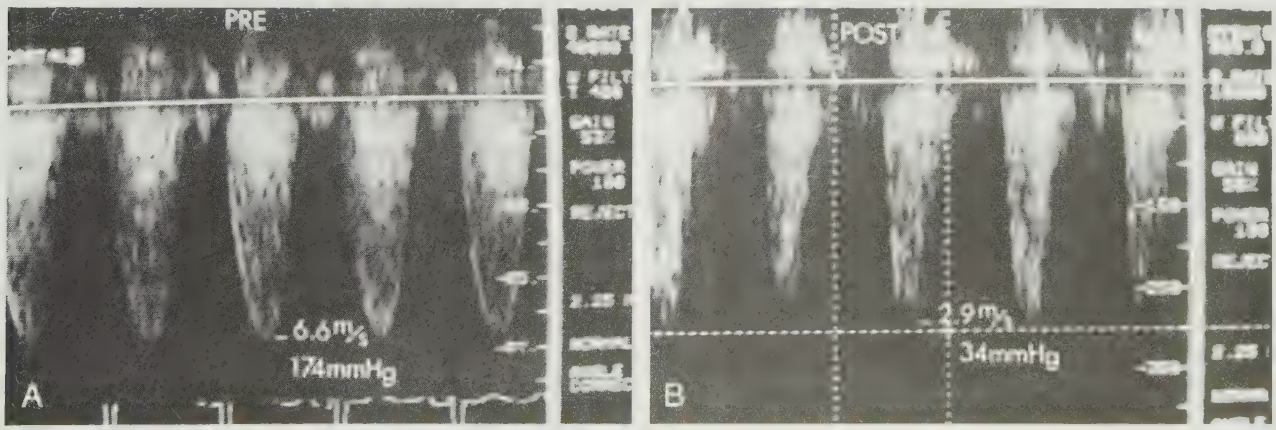

Fig. 81–19. Continuous-wave Doppler echocardiograms before (PRE) and after (POST) balloon valvuloplasty for severe pulmonary stenosis in the same infant mentioned in Figure 81–18. (A) The Doppler recording obtained from a subcostal approach before treatment demonstrated an instantaneous peak systolic transvalvular gradient of 174 mm Hg, using the modified Bernoulli equation: $PG = 4V^2$, where PG = pressure gradient and V = 6.6 m/s. (B) After balloon valvuloplasty has been completed, the peak systolic flow across the pulmonary valve decreased to 2.9 m/s. This would calculate to a postballooning transvalvular systolic gradient of approximately 34 mm Hg.

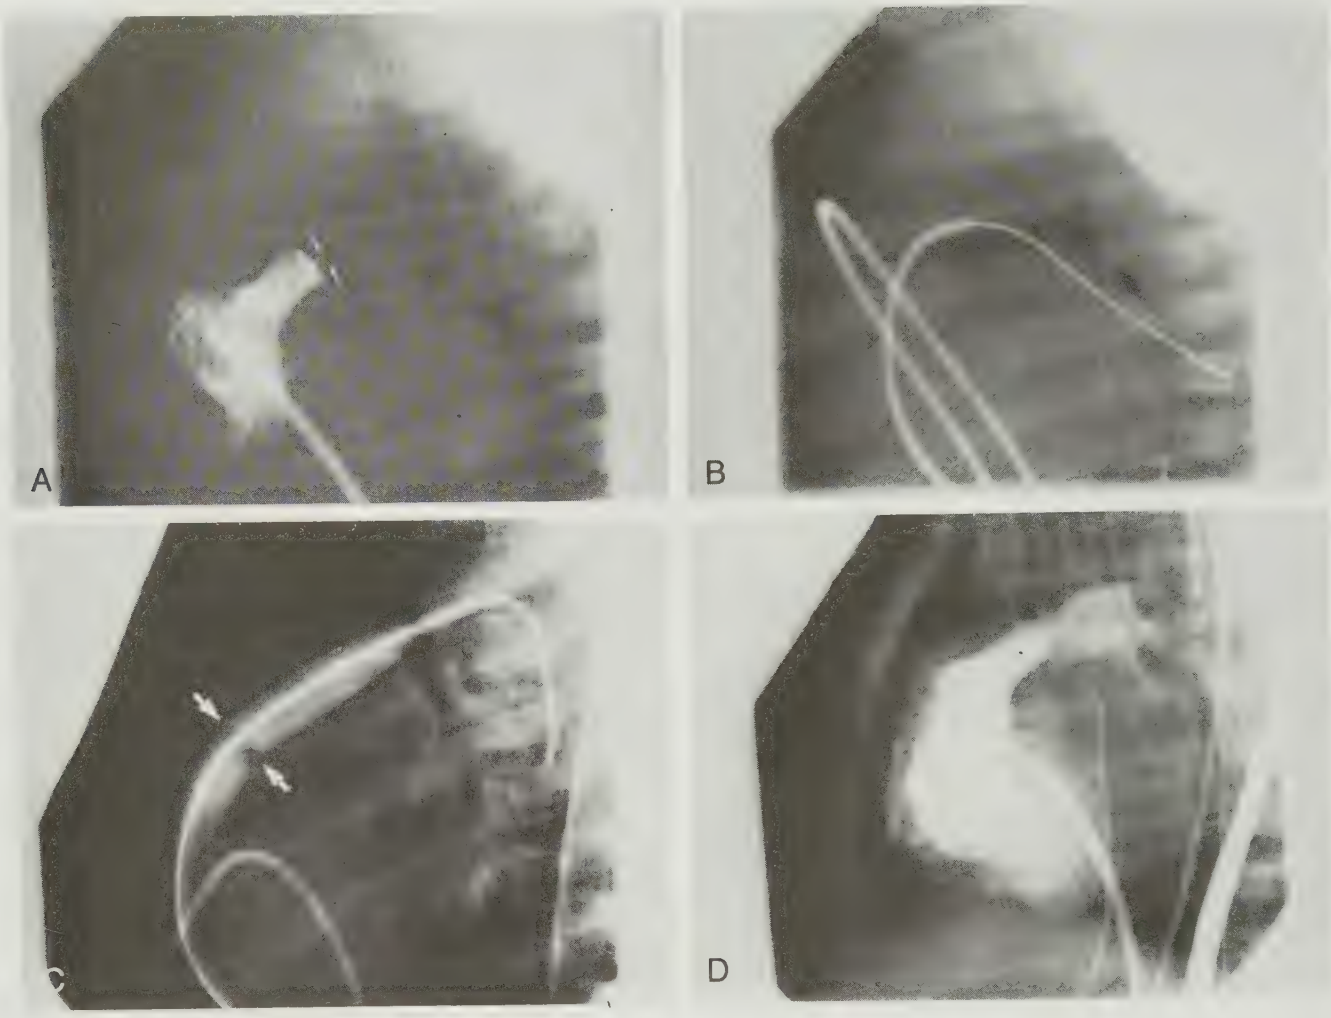

Fig. 81–20. Graduated sequential balloon valvuloplasty in a newborn with critical pulmonary valve stenosis and intact ventricular septum. (A) The lateral projection of a right ventriculogram demonstrates a tiny "jet" of prograde flow through the stenotic valve (arrows). The patient had a large patent ductus arteriosus supplying pulmonary blood flow, similar to pulmonary atresia with intact ventricular septum. (B) A guidewire was inserted across the stenotic pulmonary valve and placed into the distal pulmonary artery. An end-hole catheter was then advanced over the guide wire to dilate the pulmonary valve so that a balloon catheter could be passed through the tight orifice. (C) Next, a balloon catheter was placed across the stenotic pulmonary valve and inflated to outline the "waist" (arrows). After full inflation of the balloon, the waist disappeared. The presence of a patent ductus arteriosus is helpful to sustain pulmonary blood flow while obstructing right ventricular output during balloon inflation. (D) A repeat right ventriculogram revealed markedly improved prograde flow through the stenotic pulmonary valve.

and more cost effective than cardiopulmonary bypass for children with pulmonary stenosis.[257] However, in extremely ill infants, the closed or opened valvotomy using inflow occlusion is used as an emergency procedure. Lower mortality and morbidity with cardiopulmonary bypass for pulmonary stenosis surgery than in the past for young infants with critical pulmonary stenosis may be attributed to improved techniques for myocardial protection. These techniques are invaluable if a transannular patch or extensive infundibular resection is required in addition to pulmonary valvotomy or valvectomy.[258–261]

In rare instances, fatal right ventricular failure occurs ("suicide right ventricle") after an apparently successful valvotomy, presumably secondary to infundibular spasm.[262] It has been suggested that after adequate surgical pulmonary valvotomy, there is no need to explore and proceed with infundibular resection in patients with residual right ventricular pressure equal to systemic arterial pressure measured immediately after surgery.[263] In the same study, continuous postoperative right ventricular pressure monitoring demonstrated a 50% reduction in pressure over the first 24 hours. Propranolol may be given in an attempt to reduce infundibular narrowing and to differentiate dynamic from fixed subvalvular obstruction.[264]

When pulmonary stenosis is caused by a dysplastic valve, simple valvotomy is an inadequate surgical procedure. A partial or, more likely, a total pulmonary valvectomy is required.[265–267] In addition to removal of the thickened, immobile valve leaflets, insertion of a transannular patch is sometimes necessary because of the hypoplastic annulus and main pulmonary trunk. Patients who have undergone pulmonary valvectomy are left with at least a moderate degree of pulmonary insufficiency. Although a recent surgical study reports the long-term effectiveness and absence of symptoms at rest after five years in this patient population, there is still

concern regarding right ventricular function at rest and with exercise years after pulmonary valvectomy.[267]

The mortality from surgery is relatively low in both adults and children. In the Mayo Clinic series, the mortality rate was 4% in patients with pulmonary valve stenosis and intact ventricular septum.[268] Among 304 patients operated upon for pulmonary stenosis in the U.S. Joint Study, 9 died (3% mortality), and all of the deaths occurred in infants younger than one week of age. In the Toronto series, the surgical mortality in children younger than 12 years of age was 7%.[269] Bashour and colleagues also reported a surgical mortality of approximately 4%.[270] However, it is clear from the report of Coles and associates that the surgical risk for the neonate with critical pulmonary valve stenosis is quite high.[271] In this study, the overall hospital mortality is 42%, which was actually higher than the risk for pulmonary valve atresia with intact septum. The authors stressed the importance of establishing adequate extracardiac pulmonary blood flow in these critically ill neonates by infusion of prostaglandin E_1 or systemic-pulmonary shunt. Obviously, many of these infants had hypoplastic and/or poorly functioning right ventricles.

Postoperatively, the right ventricular pressure falls considerably. It is likely that 75% of patients with mildly elevated right ventricular pressures immediately after the operation will have a return to normal pressure after one to two years.[246] The U.S. Joint Study demonstrated that of 294 operated patients, only 10 had a right ventricular to pulmonary artery gradient of more than 50 mm Hg at recatheterization four to eight years after surgery.[76] Only one of these patients had transarterial valvotomy on cardiopulmonary bypass. At present, there is no strong evidence of restenosis. These data strengthen the argument for treatment intervention in children with resting transvalvular pulmonary gradients exceeding 50 mm Hg.

The incidence of postoperative pulmonary insufficiency varies from 57 to 90%.[76,245,272] Although this does not create immediate problems in most instances, the possibility of deleterious effects in later years from chronic diastolic overload of the right ventricle is certainly possible. A recent study demonstrated improved right ventricular function following late pulmonary valve replacement for residual pulmonary insufficiency after tetralogy of Fallot repair.[273] This issue is very controversial for the population of patients with tetralogy of Fallot surgery, and data from that population may not reflect the situation for patients with pulmonary stenosis. There are very few reports of late complications after pulmonary valve surgery. Late arrhythmias appear to be rare. We could find no cases of late sudden death in this patient population. Wright and Moller reported residual right-to-left atrial shunting following pulmonary valvotomy without closure of an atrial communication.[274] Exercise abnormalities were mentioned earlier in the chapter and appear to be more common in adults who had late repair.[147] In McNamara and Latson's study, 3 of 13 postoperative patients undergoing treadmill exercise testing demonstrated premature ventricular beats.[272]

Recreational, Occupational, and Insurability Recommendations

The pediatric cardiologist is often asked the extent to which physical activity should be restricted in the child with pulmonary valve stenosis, either treated or untreated. In 1986, a special report was issued by an American Heart Association committee representing the Council on Cardiovascular Disease in the Young stating the recreational and occupational recommendations for young patients with heart disease.[275] The committee recommended *no restriction* of physical activities, allowing endurance training, interscholastic athletics, and contact sports in all patients with operated or unoperated mild pulmonary valve stenosis. In patients with mild obstruction, occupational activity may include *very heavy work* to include a peak load of 7.6 cal/min and above, lifting of objects in excess of 100 lb, and frequent lifting and/or carrying of objects weighing 50 lb or more.

In patients with operated or unoperated moderate pulmonary valve stenosis, *light exercise* was recommended. This is to include nonstrenuous team games, recreational swimming, jogging, cycling, and golf. Allowable occupational activity is classified as *medium work*. This classification includes a peak load of 5.0 to 7.5 cal/min, lifting a maximum of 50 lb and frequent lifting and/or carrying of objects weighing up to 25 lb.

As expected, children with severe pulmonary valve stenosis with or without intervention have more restriction of activities. A recreational classification of *moderate limitation* is advised which includes attending school but no participation in physical education classes. The occupational activity category of *light work* is recommended in this group of patients. This includes a peak load of 2.6 to 4.9 cal/min, lifting 20 lb maximum, and frequent lifting and/or carrying of objects weighing up to 10 lb. Jobs that require considerable walking or standing or those that require mostly sitting with some pushing and pulling of arm and/or leg controls are acceptable.

A special task force issued recommendations regarding eligibility for competition in athletes with congenital heart disease.[276] Recommendations were as follows:

1) Patients with an unoperated peak systolic pulmonary transvalvular gradient of less than 50 mm Hg and normal right ventricular function may participate in all competitive sports.
2) Patients with an unoperated peak systolic pulmonary valve gradient of 50 mm Hg or more and/or evidence of right ventricular dysfunction can participate in low-intensity sports, including bowling, cricket, curling, golf, and riflery. Patients in this category are usually referred for balloon pulmonary valvuloplasty or alternatively for surgical valvotomy.
3) Patients with adequate operative relief of obstruction (mild pulmonary valve stenosis) and normal right ventricular function six months after surgery can participate in all competitive sports. If balloon valvuloplasty is performed, a shorter interval after relief of the gradient may apply.
4) Patients with persistent moderate-to-severe pulmonary valve stenosis after surgery should follow the same recommendations as for preoperative patients. The committee also stated that the minimal diagnostic evaluation required before a decision is made regarding participation in athletics in a patient whose electrocardiogram and physical examination suggest moderate or severe pulmonary stenosis includes measurement of gradient by cardiac catheterization and evaluation of right ventricular function by angiography, two-dimensional echocardiography, or nuclear medicine–quantitated ventricular ejection fraction. The use of

continuous-wave Doppler echocardiography may accurately predict the transvalvular gradient.

Another problem that commonly faces the patient with congenital heart disease is the ability to qualify for health and life insurance. In 1980, the Committee on Insurability of the Council on Cardiovascular Disease in the Young and representatives of the Association of Life Insurance Medical Directors of America jointly developed guidelines.[277] Children with trivial pulmonary valve stenosis (systolic gradient less than 15 mm Hg) are insurable at a standard rating. Patients with mild pulmonary valve stenosis (systolic gradient between 15 and 45 mm Hg) have standard-to-minimum substandard insurable rating. Moderate pulmonary valve stenosis (transvalvular gradient between 46 and 79 mm Hg or a right ventricular systolic pressure of 50 to 74% of systemic systolic pressure) requires a moderate-to-heavy substandard rating of insurability. Children with severe pulmonary valve stenosis (peak systolic gradient greater than 79 mm Hg or right ventricular systolic pressure greater than 74% of systemic systolic pressure) are probably uninsurable.

When assessing the patient's postoperative hemodynamics, the committee divided the group into those with excellent surgical results and those with less than excellent results. The criteria for excellent results are 1) lack of symptoms, 2) absence of cyanosis, 3) normal chest film except dilated main pulmonary trunk, 4) normal electrocardiogram or mild right ventricular hypertrophy, and 5) a peak systolic transvalvular gradient less than 25 mm Hg if catheterized. Patients who fulfill the above criteria for excellent surgical results should have a standard rating for insurability. The criteria for less than excellent surgical results are similar to the preoperative criteria for mild, moderate, and severe stenosis. Trivial-to-moderate pulmonary insufficiency does not alter postoperative classification. Patients with less than excellent surgical results are insurable at a rating that corresponds to the residual hemodynamics as classified by the preoperative state.

INTRACAVITARY OBSTRUCTION OF THE RIGHT VENTRICLE

The next portion of the chapter briefly discusses the various forms of intracavitary obstruction of the right ventricle. The two types of obstruction may be classified as primary infundibular stenosis and double-chambered right ventricle secondary to an anomalous muscle bundle.

Pulmonary Infundibular Stenosis

Background, Prevalence, Pathology, and Embryology

Primary infundibular stenosis with intact ventricular septum is a very uncommon defect; it was initially described by Elliotson in 1830.[278] This rare entity accounts for only approximately 5% of all cases of right ventricular outflow tract obstruction. Primary infundibular stenosis has been separated into two types:

1) A fibrous band at the junction of the infundibulum and main body of the right ventricle. This is the more common type and closely resembles the double-chambered right ventricle.
2) Fibromuscular obstruction directly beneath the pulmonary valve.

The proposed embryologic abnormality for both types is an arrest of bulbus cordis involution that, along with the ventricular sinus, forms the outflow tract.[25]

Pathophysiology and Manifestations

The pathophysiology of primary infundibular stenosis is similar to that already described for pulmonary valve stenosis. The clinical manifestations of these two disorders are indistinguishable from each other. The signs and symptoms depend upon the severity of obstruction and the association of other cardiac defects. The physical findings consist of a loud, systolic ejection murmur that may be accompanied by a thrill. The first sound is normal with a widely split second sound and soft pulmonary component.

Two findings that help to distinguish infundibular from pulmonary valvar stenosis are the lower precordial location of the murmur and the absence of an ejection click in infundibular stenosis. However, it is often very difficult to differentiate the two disorders clinically. The electrocardiographic features of infundibular stenosis are similar to those of pulmonary valve stenosis. Levine and Blumenthal suggested that the infundibular stenosis is more likely to progress in severity, as noted on the electrocardiogram, than is pulmonary valve stenosis.[190] With the exception of a dilated pulmonary trunk, the radiographic features of infundibular and pulmonary valvar stenosis are similar. Weyman first demonstrated the ability to differentiate obstruction at the infundibular area from that at the valve site using M-mode echocardiography.[100] The pulmonary valve usually demonstrates systolic fluttering secondary to the valve being moved by the turbulent flow from the infundibular obstruction. The A dip may be absent in severe cases. Two-dimensional, Doppler, and color flow echocardiography help considerably in distinguishing infundibular from valvar stenosis. When the infundibular stenosis is directly beneath the valve, the distinction may be difficult. However, when systolic fluttering of the valve is noted rather than doming, the diagnosis of subvalvular obstruction is much more likely. We have found the parasternal right ventricular outflow view and the subcostal inflow–apex–outflow view of the right ventricle to be very helpful. It is also possible to estimate the severity of obstruction by using continuous-wave Doppler echocardiography, but care must be taken to align the transducer parallel to the turbulent flow.

Cardiac Catheterization

During cardiac catheterization, the pullback pressure recording should be obtained by using an end-hole catheter. If the obstruction is at the junction of the main right ventricular body and infundibulum, then the pressure obtained in the subvalvular area will be equal to the pulmonary artery pressure with a higher right ventricular pressure in the main cavity. In contrast, when the stenosis is immediately beneath the pulmonary valve, the pullback pressure recording may be indistinguishable from pulmonary valve stenosis. A selective right ventriculogram with the anteroposterior camera in the standard position or with 40° cranial angulation and a straight lateral projection demonstrates the site of infundibular obstruction quite nicely. The narrowing is usually constricted during systole, with a normal pulmonary valve, and no poststenotic dilatation of the main pulmonary artery is noted.

Differential Diagnosis

The list of differential diagnoses is long and very similar to that for pulmonary valve stenosis. The murmur most likely to be confused with infundibular stenosis is from a ventricular septal defect. The lower location of the infundibular stenosis murmur and absence of an ejection click makes it difficult to differentiate this

diagnosis from ventricular septal defect. Characteristics of the murmur that would favor the diagnosis of infundibular stenosis are ejection systolic murmur, radiation to pulmonary arteries, and a widely split second sound with a soft pulmonary component. If the murmur is holosystolic with a left ventricular lift and diastolic flow rumble over the mitral valve, then the diagnosis of ventricular septal defect is likely. The electrocardiogram and chest roentgenogram may be helpful in distinguishing between these two defects. Echocardiography is frequently necessary to make the distinction among infundibular obstruction, pulmonary valve stenosis, and ventricular septal defect.

Treatment

Although infundibular stenosis has reportedly been treated with balloon dilation, there is a significant risk of valve avulsion and intramyocardial hemorrhage, thus limiting the applicability of dilation techniques at this time.[213] Therefore the treatment of choice in significant primary infundibular stenosis is surgical resection of the fibrotic area or hypertrophic muscle.[38,279,280] It is occasionally necessary to use a right ventricular outflow tract patch with some forms of infundibular stenosis. Because progression of severity in obstruction may be more rapid with this disease, closer followup may be warranted. Appropriate antibiotic prophylaxis is necessary for both operated and untreated primary infundibular stenosis with intact ventricular septum.

Double-Chambered Right Ventricle

Background, Prevalence, Pathology, and Embryology

Since Lucas described the first cases of double-chambered right ventricle in 1962 as a new entity to be separated from other forms of right ventricular outflow tract obstruction, more than 100 cases have been reported.[281–287] The obstruction is caused by anomalous bands of muscle oriented so as to divide the right ventricular cavity into a proximal high-pressure chamber and a distal low-pressure chamber.[288–293] The anomalous muscle bundles are hypertrophic, constituting a pyramid-shaped mass running between the ventricular septum inferior to the insertion site of the tricuspid valve septal leaflet to the right ventricular anterior free wall. There are commonly two bundles, the ventral and the dorsal. The ventral bundle is smaller, is more superficial, and attaches to the right ventricular wall adjacent to the septum. The dorsal bundle is larger and thicker and has its attachment at the anterior papillary muscle base.[35]

In contrast to tetralogy of Fallot, the anomalous muscle bundles cross the right ventricular cavity and lie proximal to the infundibulum. They frequently occur at the sinus portion of the right ventricle or along the distal or apical portion of the inflow. Although the moderator band is a normal structure that may be confused with anomalous muscle bands, there are some noteworthy differences. The orientation of the anomalous bands are different from that of the moderator band. The anomalous muscle bundles have their septal attachments more basally near the tricuspid valve annulus, while the insertion site of the moderator band is in the apical third of the ventricular septum. Both types of bands attach to the right ventricular free wall, but the unobstructive moderator band lies toward the septal side of the cavity, while the obstructive anomalous bands cross the main cavity.

There has been speculation regarding the etiology of these anomalous muscle bundles. Keith suggested that the embryologic explanation for this malformation is an arrest of the incorporation of the primitive bulbus cordis into the body of the right ventricle.[25] An improper expansion of the bulboventricular junction may result in the incomplete fusion of the bulbar and endocardial cushions that are responsible for closing the superior ventricular septum. This theory would explain the common occurrence of an associated ventricular septal defect, which is observed in up to 93% of cases.[287] Some investigators think that isolated forms of double-chambered right ventricle do not exist, but rather a previously patent ventricular septal defect closed spontaneously.[284,294] Others attributed this anomaly to persistence of early myocardial cells or trabeculations.[281,286] It has also been postulated that the obstruction in the double-chambered right ventricle is caused by an elevated origin of a hypertrophied moderator band from the septal band.[284] In most severe forms, this band originates near the crista supraventricularis, resulting in an unusual and different orientation from that of the normal moderator band. Rowland and co-workers view this muscular tissue as "anomalous" only in representing arrest in development of the right ventricle.[284] Other groups support the hypothesis of inadequate bulbar incorporation because of the association of discrete subaortic stenosis with this lesion, as well as with ventricular septal defect.[284,294,295] Bashour and co-workers reported double-chambered right ventricle with a fibromuscular diaphragm similar to that found in subaortic stenosis.[296]

Pathophysiology and Manifestations

The pathophysiology of this disease is similar to that of the other forms of intracavitary obstruction of the right ventricle with intact ventricular septum. The obstruction is between the inflow and outflow portions of the ventricle, and there may be a further compromise in the diameter of this area during ventricular systole. A nonobstructive anomalous muscle bundle in infancy may become obstructive with time.[284,286,289] Clinically, patients with double-chambered right ventricle are similar to those with pulmonary valvar or infundibular stenosis. Since ventricular septal defect is so commonly present, this may influence the clinical manifestations. A prominent diamond-shaped systolic murmur with thrill is frequently heard along the left lower sternal border. It may be indistinguishable from the murmur of infundibular stenosis. A significant left-to-right shunt from the ventricular septal defect should be suspected if a mid-diastolic flow rumble is present over the mitral valve area. Typically, a click is absent, and the pulmonary component of the second sound is normal.

The chest roentgenogram is similar to that of infundibular stenosis unless a significant ventricular septal defect is also present. In most patients, the electrocardiographic patterns are those of right ventricular hypertrophy. A recent study by Li and colleagues demonstrated the presence of an upright T wave in lead V_3R as the only finding suggestive of right ventricular hypertrophy in as many as 40% of patients with double-chambered right ventricle.[291] In milder cases of obstruction, a normal electrocardiogram was seen initially, but there was progression to right ventricular hypertrophy as the muscular obstruction increased.[289] However, normal electrocardiograms have been reported in patients with severe obstruction.[297] Folger reported a reproducible electrocardiographic appearance with double-chambered right ventricle to be a right superior vector orientation and rightward displacement of the electrocardiographic right ventricular hypertrophy pattern.[298] He later

ascribed this abnormality to a right ventricular pouch noted on angiography.[299]

Echocardiography may be very helpful in diagnosing double-chambered right ventricle. Initially, Fermont and colleagues stated that the diagnosis of this disorder was suggested by the presence of the following M-mode features: easy visualization of the pulmonary valve, premature closure and systolic fluttering of the pulmonary valve, and false septoaortic discontinuity.[300] Two-dimensional echocardiography has improved diagnostic accuracy in this lesion.[287,297,301,302] Direct imaging of the anomalous muscle bundle using the subcostal inflow–apex–outflow view and the subcostal short-axis view has improved diagnostic capabilities and allowed better understanding of the unusual intracardiac anatomy (Fig. 81–21).

Cardiac Catheterization

Cardiac catheterization is frequently necessary for more definitive assessment. The systolic pressure in the distal portion of the double-chambered right ventricle is usually normal and equal to the pulmonary artery systolic pressure. The gradient across the anomalous muscle bundle is detected by placing the catheter into the proximal inflow portion of the right ventricle and then advancing to the distal outflow chamber. Since it is technically quite easy to place the catheter from the right atrium directly into the right ventricular outflow tract, the pediatric cardiologist must be aware of potentially "missing" the high-pressure inflow portion of the ventricle. Therefore we advise placing the catheter into the right ventricular inflow and apical region in all patients undergoing cardiac catheterization for ventricular septal defect. Selective right ventriculography is imperative for diagnosis and may be performed in the standard anteroposterior and lateral projections or with cranial angulation of the anteroposterior camera.[303–305] We prefer to perform the injection with the catheter in the high-pressure portion of the double-chambered right ventricle for better anatomic detail of the anomalous muscle bundle (Figs. 81–22 and 81–23A, B). However, Folger described a contractile, right ventricular outflow pouch in approximately 60% of patients that was best demonstrated with the low-pressure distal chamber as the injection site.[299] Although the filling defect secondary to the anomalous muscle band is constant throughout the cardiac cycle, it is best appreciated during ventricular systole. A left ventricular angiogram with left anterior oblique and cranial angulation is important to rule out an associated ventricular septal defect or subaortic valve membrane. Since Danilowicz and Ishmael reported an extraordinarily high incidence of renal anomalies in patients with anomalous right ventricular muscle bundle (43%), we recommend close inspection of the kidneys, ureters, and bladder after cineangiography has been completed.[297]

Treatment

The treatment of double-chambered right ventricle with significant obstruction is surgery.[291–293] We do not recommend attempting balloon dilation of these obstructions. Warden and associates noted at the time of surgery that during ventricular contraction, a "dimple" on the usually smooth right ventricular surface suggested the presence of an anomalous muscle bundle.[293] The "dimple" corresponds to the parietal attachment of the ventral limb of the muscle band and is located midway between the base and apex near the anterior interventricular groove. A right ventriculotomy is necessary, and transection of the parietal and septal origin sites must be performed first. It is extremely important to have complete exposure of the anterior papillary muscle and tricuspid valve to avoid injury during the resection of the insertion sites of the anomalous muscle band.[293] The associated ventricular septal defect is also closed at the time of operation.

Although the long-term prognosis for these patients is unknown,

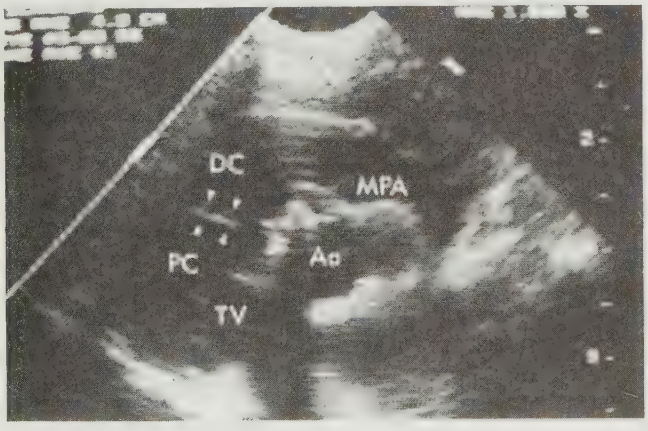

Fig. 81–21. A two-dimensional echocardiogram in a patient who developed double-chambered right ventricle after surgical closure of a ventricular septal defect. We used a modified subcostal inflow–apex–outflow view. The tricuspid valve (TV) leaflets are seen leading into the proximal chamber (PC) of the right ventricle. This chamber is the high-pressure portion of the ventricle. The anomalous muscle bundle (arrows) is seen dividing the right ventricle into a proximal and a distal chamber (DC). This low-pressure outflow chamber empties through the pulmonary valve into the main pulmonary artery (MPA). A bright echo representing the ventricular septal defect patch is seen near the aorta (Ao) at approximately 9 to 11 o'clock.

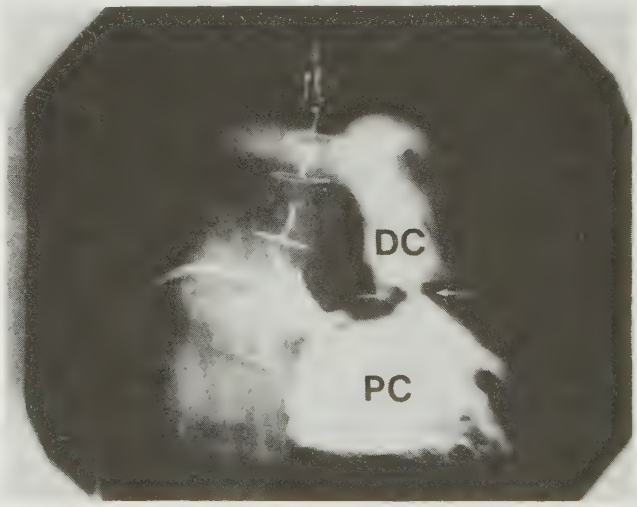

Fig. 81–22. A right ventriculogram in a child with double-chambered right ventricle after closure of a ventricular septal defect in the same patient as in Figure 81–21. A large fibromuscular ridge (arrows) is shown dividing the right ventricle into a high-pressure proximal chamber (PC) and a low-pressure distal chamber (DC). The pulmonary valve is seen widely open in systole without dilatation of the main pulmonary artery.

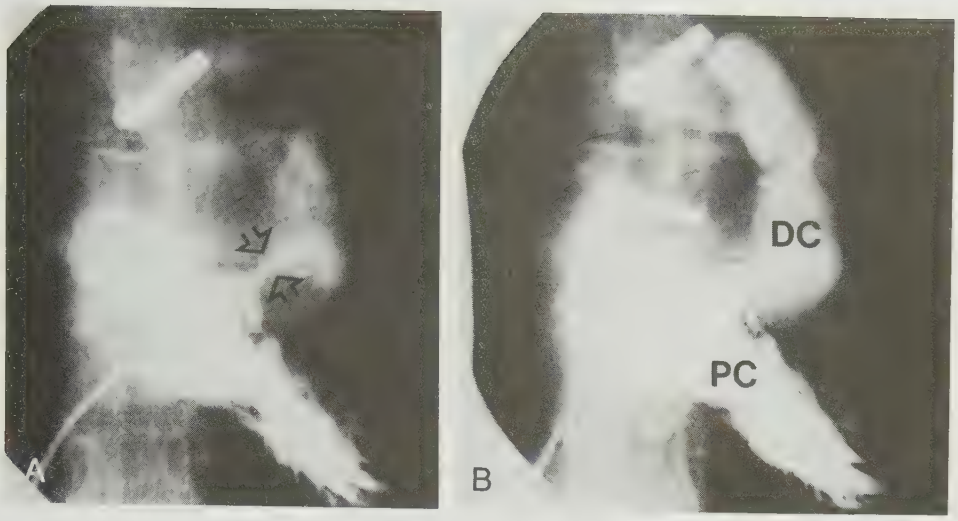

Fig. 81–23. A right ventriculogram in a teenager with a double-chambered right ventricle who had a ventricular septal defect repaired in early childhood. (A). The initial injection is into the proximal chamber with a discrete "jet" of contrast material streaming into the distal chamber as depicted by the arrows. (B). After several more cineangiograph frames, both the proximal and distal chambers (PC, DC) are well seen. It is easy to understand how the term "double-chambered right ventricle" came into existence after seeing this angiocardiogram.

the short-term surgical results appear good. In the untreated condition, double-chambered right ventricle secondary to an anomalous muscle bundle appears to be a progressive disease. Patients with this disorder should be followed as outpatients every six months as infants and young children and yearly as older children. The electrocardiogram and echocardiogram should prove useful in detecting changes in the severity of obstruction and selecting patients for cardiac catheterization and surgery. Appropriate antibiotic prophylaxis for infective endocarditis is indicated.

PULMONARY ARTERY STENOSIS

Background

Obstruction in the pulmonary arterial tree distal to the pulmonary valve has been described by using various terms: partial atresia or hypoplasia of the pulmonary arteries, supravalvular pulmonary stenoses, coarctation of the pulmonary arteries, and postvalvular, multiple, or peripheral pulmonary stenoses. A number of classifications have been made, but those of Smith[306] and Franch and Gay[307] are the most widely used. They identify the area of the pulmonary artery most severely affected, such as the proximal main pulmonary artery, bifurcation of the main pulmonary artery, distal pulmonary arteries, or various combinations. Rowe described another classification based upon simple or complicated cardiac malformations as well as the site of obstruction.[308] Simple pulmonary artery stenoses were classified as isolated or pulmonary artery obstruction associated with simple cardiac diseases. Complex pulmonary artery stenoses usually have tetralogy of Fallot or transposition of the great arteries associated with the obstruction. Both simple and complex stenoses are further separated into sites of obstruction: central, peripheral, or intermediate. The stenoses may be unilateral or bilateral.

Prevalence

The overall frequency of pulmonary arterial stenosis is an estimated 2 to 3% of congenital heart disease.[309,310] Isolated pulmonary arterial stenosis was initially reported by Mangars in 1802 and later by Schwalbe.[311] There have been numerous reports of cases since this early report.[312–323] In one third of cases, the pulmonary artery stenosis is an isolated defect, but two thirds of patients have associated cardiac defects. The most frequent associated defects are pulmonary valve stenosis and ventricular septal defect.[9,324] Tetralogy of Fallot is also commonly seen with hypoplasia of the pulmonary branches.[9,320] If rubella syndrome is present, patent ductus arteriosus and atrial septal defect are also usually present.[316,325,326] A syndrome (Williams) with supravalvular aortic stenosis, multiple pulmonary arterial stenoses, elfin facies, and mental retardation has been described.[161,162,327] Other syndromes in which pulmonary artery stenoses are present include Noonan's, Alagille (arteriohepatic dysplasia), Ehlers-Danlos, cutis laxa, and Silver's syndromes.[29,308,318,322,328]

Embryology and Pathology

The pathogenesis of pulmonary artery stenosis is unknown, although multiple factors and many types of pathologic changes may produce vessel narrowing. A teratogenic agent may interrupt the development of any segment of the pulmonary arterial tree; for example, rubella virus may interfere with normal formation of elastic layers of the tissue.[329] The stenoses may be caused by a ring-like membrane, fibrous intimal and medial thickening, or abnormality of elastic tissue properties. In general, two thirds of patients demonstrate stenosis of the main pulmonary trunk, its bifurcation, or its main branches. Distal vessel dilatation occurs if the stenosis is localized, while only minimal poststenotic dilatation is present if an elongated constriction is present. Prestenotic dilatation of the main pulmonary trunk is very uncommon.

Pathophysiology

The pathophysiologic process of pulmonary artery stenosis results in elevation of the right ventricular and pulmonary arterial pressure proximal to the obstruction. If the stenosis is central, the right ventricular stroke volume cannot be increased readily secondary to the limited proximal pulmonary trunk volume capacity. With severe stenosis, the ejection time of the right ventricle is prolonged, a feature that explains the delayed pulmonic component of the second sound. If there is no associated pulmonary valve stenosis, the length and magnitude of vessel narrowing determine the contractile mechanics of the right ventricle. Orell and coworkers noted that closure of the pulmonary valve may occur

earlier than, and sometimes at the same time as, closure of the aortic valve if there are severe multiple peripheral stenoses of small pulmonary arterial branches.[330] In the absence of increased pulmonary flow, the right ventricular pressure is normal in unilateral pulmonary artery stenosis. The contralateral pulmonary circulation is able to accommodate the cardiac output without increase in pressure. It is uncertain, under conditions of normal pulmonary flow, whether the absolute pressure difference between the main trunk and the distal pulmonary artery is proportional to the severity of obstruction. However, it is known that the diastolic pressure difference between the main trunk and the pulmonary artery branch is directly proportional to the severity of obstruction.

Manifestations

The clinical features of pulmonary artery stenosis may easily be masked by the other associated cardiac defects. However, close inspection and auscultation reveal a systolic ejection murmur heard over the pulmonary area but better transmitted to the back and lateral lung fields. A click is usually absent unless pulmonary valve stenosis is also present. A continuous murmur may be present in up to 10% of patients and indicates that the diastolic gradient across the obstruction is significant.[315] Though the murmur varies according to severity, it usually peaks in late systole. The first sound is normal, while the second sound is usually normal in intensity and width of splitting. In patients with significant multiple peripheral pulmonary arterial stenoses, the second sound in the pulmonary artery may be quite loud and confused with pulmonary hypertension. In these patients, the presence of continuous murmurs in the back and axilla should lead one to the correct diagnosis.

A transient murmur resembling that of pulmonary arterial stenosis is frequently heard in healthy, premature infants during the first few months of life and is considered "physiologic."[331] This murmur has also been reported in young full-term infants as well. It is believed to be secondary to the disparity of main pulmonary trunk size, diameter of pulmonary branches, and the acute angle between the trunk and the branches.[332]

Patients with mild-to-moderate arterial obstruction are asymptomatic, while those with severe stenosis may have dyspnea on exertion, easy fatigability, and occasionally right-sided heart failure. Cyanosis may occur if there is an intracardiac or extracardiac right-to-left shunt. Progression from relatively mild to severe symptomatology occurred in two reported fatal cases in less than two to four years.[323,330]

Electrocardiogram, Roentgenogram, and Echocardiogram

The electrocardiogram in mild cases is usually normal. Varying degrees of right ventricular hypertrophy are present in patients with moderate-to-severe pulmonary artery stenosis and are indistinguishable from those of pulmonary valve stenosis (Fig. 81–24). In a group of infants with rubella syndrome, a high frequency of left-axis deviation was noted.[333] A similar electrocardiogram was reported in infants with Noonan's syndrome.

The radiographic features of pulmonary artery stenosis are unremarkable. The chest roentgenogram is normal unless there are other significant associated cardiac defects (Fig. 81–25).

The echocardiogram may be helpful in the diagnosis of pulmonary arterial stenosis and other associated cardiac defects. However, there are several caveats. The more distal pulmonary artery branches cannot be adequately imaged for diagnostic purposes. As Tinker and associates reported, we have also found the parasternal short-axis and suprasternal/supraclavicular short-axis views to be the most helpful in imaging the main pulmonary trunk and right and left branches.[334] Doppler echocardiographic estimation of gradient across the stenosis is extremely difficult and frequently inaccurate. Color flow mapping may improve the accuracy of qualitative assessment. If there is evidence of a significant systolic gradient, right ventricular hypertension and hypertrophy, or significant tricuspid, and/or pulmonary insufficiency, then cardiac catheterization is recommended.

It is possible that computerized tomography, magnetic resonance imaging, and dynamic spatial reconstruction may be useful in the anatomic evaluation of pulmonary arterial stenosis. A recent report utilized chest computerized tomography to diagnose a bronchogenic cyst causing external compression of the pulmonary artery.[335] We have recently utilized nuclear medicine lung perfusion/ventilation scans in patients being considered for interventional therapy (Fig. 81–26). This test has helped to "quantitate" changes

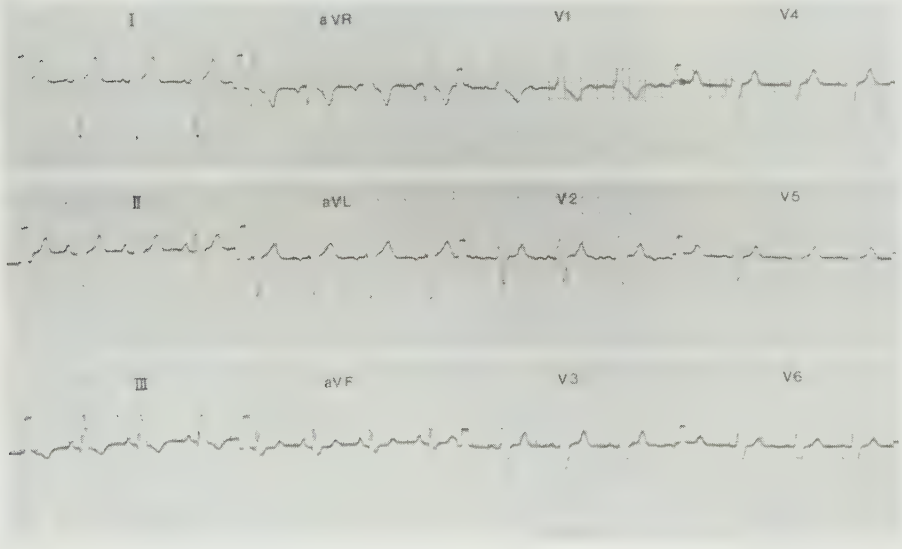

Fig. 81–24. An electrocardiogram in an adolescent boy with severe peripheral pulmonary artery stenosis secondary to Williams syndrome. Note that the precordial leads V_1 to V_6 are half-standard. Right bundle branch block versus severe right ventricular hypertrophy is observed.

Fig. 81–25. The chest film in a patient with severe peripheral pulmonary artery stenoses is quite unremarkable. The heart size is normal, and the pulmonary vascular markings are within the range of normal. The chest roentgenogram does not reflect the severity of pulmonary artery stenosis.

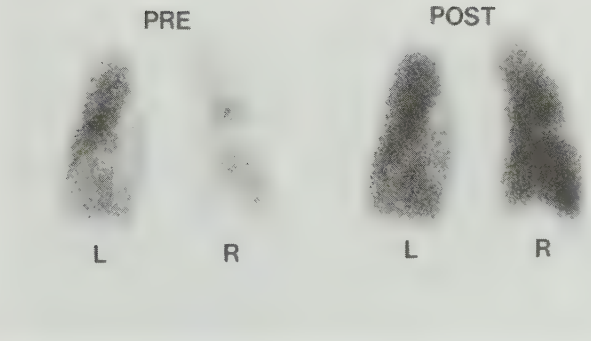

Fig. 81–26. A nuclear medicine perfusion scan in a patient undergoing balloon pulmonary angioplasty for right pulmonary branch stenosis. The views are from the posterior with the right lung (R) and left lung (L) labeled. Before angioplasty (PRE), there was differential perfusion of the lungs: 63% to the left, 37% to the right. After balloon dilation of the stenotic right pulmonary artery (POST), the perfusion to the right lung significantly increased to 52%, while the left lung perfusion was 58%. The use of perfusion/ventilation scans may help to quantitate the effects of balloon pulmonary arterioplasty.

in pulmonary blood flow, both globally and segmentally, before and after balloon pulmonary angioplasty.

Cardiac Catheterization

Cardiac catheterization is usually required for precise physiologic and anatomic diagnosis of pulmonary arterial stenosis. Particular attention needs to be paid during slow, pullback pressure recordings from the distal pulmonary arteries to the right ventricle using an end-hole catheter. In the absence of increased pulmonary blood flow, systolic pressure gradients greater than 10 mm Hg should be considered abnormal. Exceptions to this rule are in premature and young infants with a discrepant size in pulmonary branches and main pulmonary trunk or when the catheter is relatively large in comparison to the vessel diameter.[322] With isolated, unilateral stenosis, the pressure gradient is found at the site of obstruction with a normal pressure in the proximal pulmonary artery segment.

A peculiar appearance of the main pulmonary artery pressure pulse in patients with bilateral stenoses has been shown by Agustsson and colleagues.[312] The systolic portion of the main pulmonary artery pulse is identical to that of the right ventricle. However, while the diastolic pressure is normal, the dicrotic notch is abnormally deep with a flattened diastolic descent after pulmonary valve closure that appears to be proportional to the severity of distal obstruction. Rowe suggested that the diagnosis of bilateral pulmonary arterial stenosis should be suspected by the appearance of the main pulmonary artery pressure pulse alone.[308] Agustsson and colleagues attributed this characteristic pulse contour proximal to the stenosis to altered function of the pulmonary trunk.[312] A relatively nonelastic pulmonary trunk with thick, fibrotic walls becomes an extension of the right ventricular outflow tract. As long as the pulmonary artery pressure distal to the narrowing is less than the right ventricular pressure, the pulmonary valve remains open. As the obstruction sites are more peripherally located, this peculiar pressure pulse in the main pulmonary trunk becomes less obvious. When the stenoses are severe and more peripherally located, the proximal pressure pulse contour is indistinguishable from that of primary pulmonary hypertension. It is important to remember that the presence of associated pulmonary valve stenosis may negate the use of the main pulmonary trunk pressure pulse as a predictor of severity of peripheral stenoses.

Angiocardiography is the single best tool in delineating pulmonary arterial stenosis (Figs. 81–27A, B and 81–28A, B). Although a right ventriculogram is frequently performed, selective pulmonary arterial injections proximal to the site of obstruction are imperative. In most instances, 40° cranial angulation with or without appropriate obliquity is necessary in the anteroposterior projection with a straight lateral view.[336] Angiography has made it possible to classify the various types of obstruction.[307] It has also allowed the diagnosis of pulmonary arterial stenoses in complicated congenital heart disease to be made, even when it was not suspected from other studies. One should consider performing left ventricular or aortic angiography in these patients because of the possibility of associated systemic arterial lesions.

Differential Diagnosis

The differential diagnoses for pulmonary arterial stenosis are similar to those already mentioned for pulmonary valve obstruction. The characteristic radiation of the systolic ejection murmur

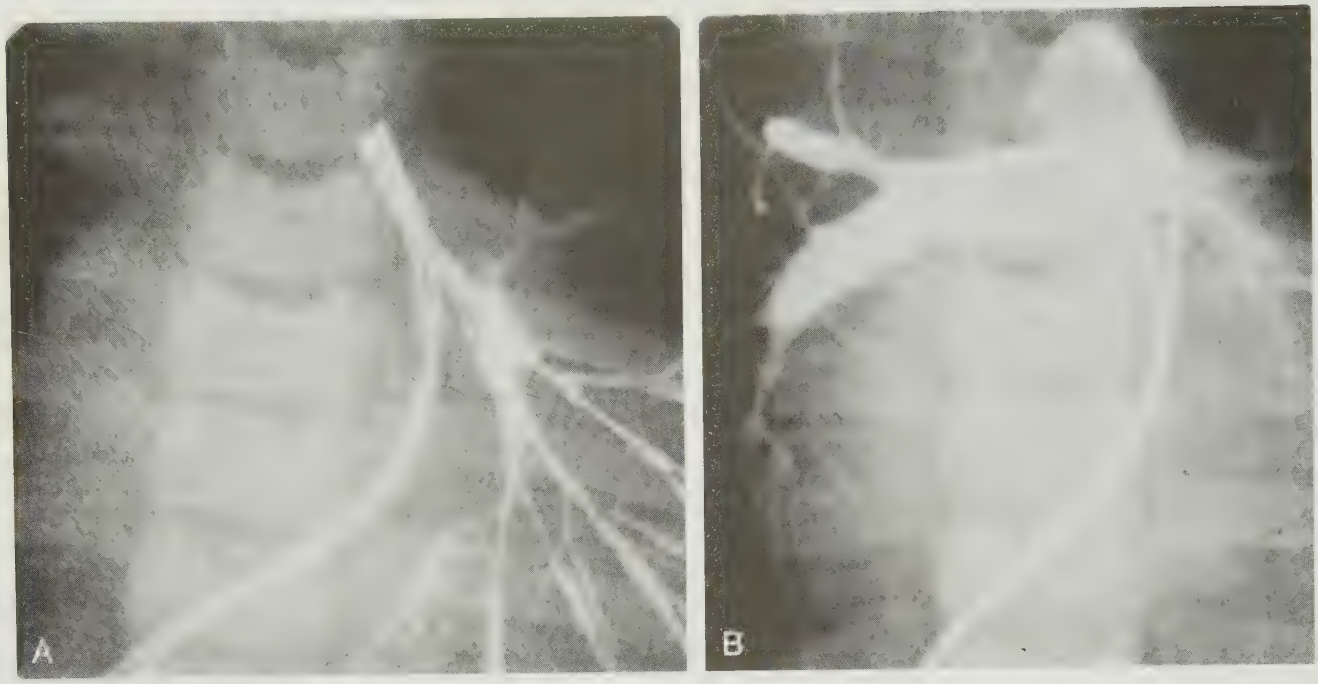

Fig. 81–27. Selective pulmonary angiograms in a child with severe peripheral pulmonary artery stenoses. (A). A left pulmonary arteriogram demonstrates severe, diffuse stenoses of all segments of the distal pulmonary arterial tree. Note the long hypoplastic segments and widespread severity. (B). The right pulmonary arteriogram also confirms complete distal involvement of the entire segmental arteries. Unfortunately, the results of balloon pulmonary angioplasty were unrewarding, and the patient continued to exhibit suprasystemic right ventricular pressure with cyanosis and right-sided congestive failure. No etiology has been found for this severe disease.

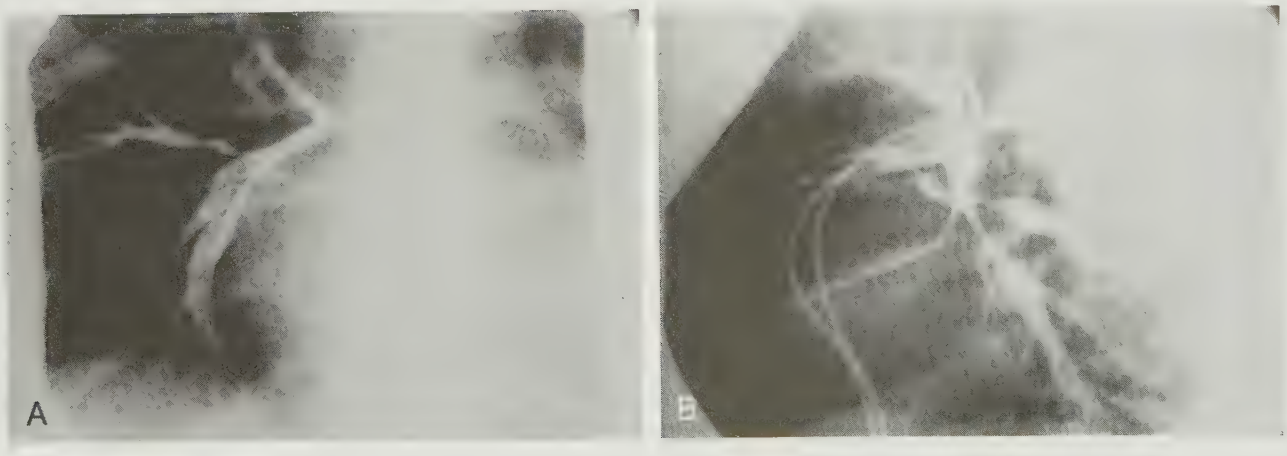

Fig. 81–28. Selective pulmonary arteriogram in a young man with Williams syndrome. (A) A right pulmonary angiogram demonstrates multiple areas of stenoses at the bifurcation of the distal arteries with varying degrees of poststenotic dilatation. (B) The lateral view of a selective left pulmonary artery injection demonstrates the symmetry in distal pulmonary arterial stenoses with Williams syndrome. There is an almost "starburst" appearance to the pulmonary arteries. Multiple stenoses were dilated by balloon, but the right ventricular and main pulmonary arterial pressures remained significantly elevated.

to the back and lateral lung fields should alert the physician to this diagnosis. Continuation of the murmur into diastole[315] may cause confusion with an incorrect clinical diagnosis of patent ductus arteriosus or pulmonary arteriovenous fistula. A family history of maternal rubella, familial congenital heart disease, or prolonged neonatal jaundice is important to consider. The phenotypic features of Noonan's or Williams syndrome are also important to note. The presence of tetralogy of Fallot or pulmonary valve stenosis should alert the pediatric cardiologist to the possibility of associated pulmonary arterial stenosis.

Natural History

The natural history of isolated pulmonary artery stenosis is generally benign.[337] However, multiple and peripheral stenoses carry a potentially poor prognosis. Orell and colleagues described complications including pulmonary hypertension, right ventricular failure, pulmonary artery thrombosis, and poststenotic aneurysmal dilatation with rupture and hemoptysis.[330] Progressive increase in the severity of pulmonary artery stenosis occurs and may be rapid. The relatively high incidence of thrombosis within the pulmonary arterial tree as the disease advances has led to the suggestion of prophylactic anticoagulation in selected cases.[313] Death in early infancy and later childhood has also been reported.[338] Prophylaxis against infective endocarditis is recommended for patients with anatomic pulmonary artery stenosis.

Treatment

Balloon Pulmonary Angioplasty

Because of the poor surgical results in the treatment of isolated pulmonary artery stenosis and complicated stenoses associated with other forms of congenital heart disease such as tetralogy of Fallot, an alternative approach to this disease was undertaken in 1980. Martin and co-workers described the first use of percutaneous transluminal balloon angioplasty to treat peripheral pulmonary stenosis in a postoperative 18-year-old after repair of pulmonary atresia with ventricular septal defect.[339] Following that report, Lock and co-workers described the use of transluminal balloon angioplasty in the treatment of newborn lambs with experimentally produced pulmonary artery branch stenosis.[215] With their laboratory experience, these same workers instituted a clinical protocol for balloon angioplasty of hypoplastic and stenotic pulmonary arteries.[218] Soon after this clinical study, several other authors reported their results with this procedure.[211,220,225,340]

The protocol for balloon angioplasty for peripheral pulmonary artery stenosis is similar to that previously described for pulmonary valve stenosis (Fig. 81–29A, B, C). There are some notable differences in technique, however. With peripheral pulmonary stenosis, a balloon diameter that is three to four times the diameter of the most stenotic segment of pulmonary artery is chosen. After proper positioning of the balloon, inflation is performed until the "waist" or "hourglass" disappears or until 4 to 6 atmospheres of pressure are achieved. The pressure is held in the balloon for a maximum of 30 seconds, unlike the rapid inflation–deflation time of less than 7 seconds used with pulmonary valvuloplasty.[341] Lock and colleagues have recommended not exceeding 6 atmospheres of pressure during inflation, since fatal pulmonary artery rupture occurred when pressure of 7 to 8 atmospheres was used.[218,342] After dilation, a second angiogram is performed by advancing an end-hole angiographic catheter over the guidewire that is left in place. Since perforation of the pulmonary artery has been reported when a straight guidewire is used, we recommend the use of the more flexible J-shaped wire. The major limitation of this procedure appears to be the inability to advance the balloon angioplasty catheter across the stenotic lumen.

The morphologic changes in the pulmonary arteries after percutaneous balloon angioplasty have been studied.[220,342] There were significant intimal and medial tears in all successful cases; at times these extended through the adventitia. At the site of the tear, a gap in the wall of the vessel representing up to 25% of the vessel circumference was commonly found. This gap was contained only by stretched adventitia. After several months, these gaps filled in with collagen and elastic fibers and healed in an open position, covered by thickened adventitia. One vessel demonstrated post-angioplasty intimal proliferation with restenosis of the lumen. Pathologic evaluation of the fatally ruptured hypoplastic left pulmonary artery revealed intimal tears and a 3 to 5 mm laceration at the rupture site.[342]

The results of balloon angioplasty for peripheral pulmonary artery stenosis have certainly been less spectacular than those for pulmonary valve stenosis. In Lock's original series, the balloon dilation was successful in five of seven patients.[218] In a later report, only five of thirteen patients had successful dilation of the stenotic segment documented by a significant drop in pressure gradient and increase in diameter of stenotic area.[220] Foker and co-workers attempted intraoperative balloon dilation of peripheral pulmonary artery stenosis in four patients with severely hypoplastic pulmonary arteries, and three patients improved.[343] Dilation angioplasty appears to increase both the vessel diameter and the blood flow through hypoplastic arteries.[218] Increasing perfusion past such vessels is unlikely to occur after a conventional operative approach. Haworth and co-workers noted that direct surgical anastomosis into a hypoplastic pulmonary artery generally uncovered stenosis distal to the mediastinum.[344] McGoon and co-workers noted that such distal stenoses are usually confined to the origins of the lobar arteries, a region out of sight for the surgeon but within reach of the balloon.[345] Thus balloon angioplasty in stenotic first- and second-generation pulmonary arterial branches appears to be the best approach to salvage hypoplastic pulmonary arteries.[218] Lock also suggested that since intra-acinar arteries of children with congenital pulmonary artery stenosis are decreased in number and the growth of these vessels appears to be greatest in the first two years of life, balloon angioplasty might need to be performed before two years of age for the best long-term results.[218,346–348]

Potential complications from this procedure include vascular rupture from an oversized balloon, perforation of a vessel from the guidewire or catheter tip, complete obstruction of the main pulmonary artery and right ventricular output during balloon dilation of proximal branch stenosis, pneumothorax, late development of aneurysms, and accelerated atherosclerosis.

Balloon angioplasty for pulmonary arterial stenosis can provide significant hemodynamic relief to a small group of patients in whom conventional operative intervention is unlikely to be successful. However, because of definite risks involved with the procedure, we routinely type and crossmatch for potential blood transfusion in all patients. In addition, we recommend that surgical and operating room "standby" be available while the balloon angioplasty procedure is being performed in the catheterization

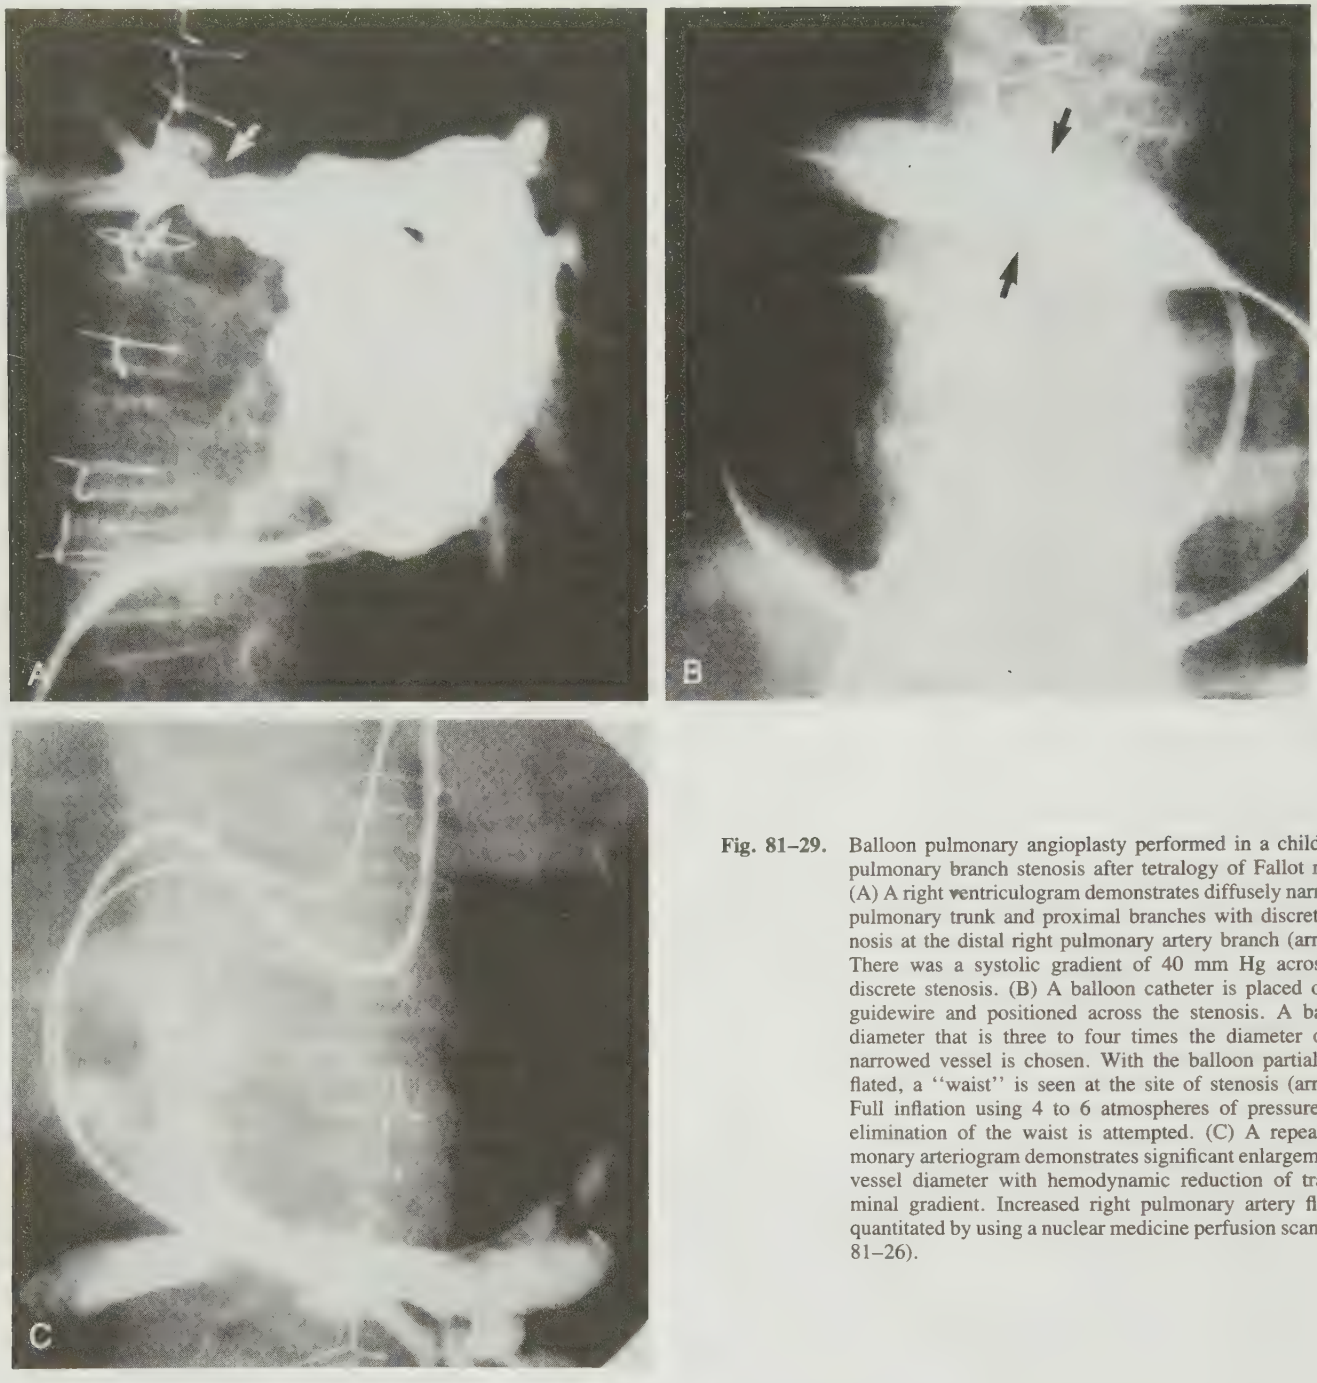

Fig. 81–29. Balloon pulmonary angioplasty performed in a child with pulmonary branch stenosis after tetralogy of Fallot repair. (A) A right ventriculogram demonstrates diffusely narrowed pulmonary trunk and proximal branches with discrete stenosis at the distal right pulmonary artery branch (arrows). There was a systolic gradient of 40 mm Hg across the discrete stenosis. (B) A balloon catheter is placed over a guidewire and positioned across the stenosis. A balloon diameter that is three to four times the diameter of the narrowed vessel is chosen. With the balloon partially inflated, a "waist" is seen at the site of stenosis (arrows). Full inflation using 4 to 6 atmospheres of pressure with elimination of the waist is attempted. (C) A repeat pulmonary arteriogram demonstrates significant enlargement of vessel diameter with hemodynamic reduction of transluminal gradient. Increased right pulmonary artery flow is quantitated by using a nuclear medicine perfusion scan (Fig. 81–26).

laboratory. We also recommend that the more distal stenotic lesions be dilated first, followed by angioplasty of the proximal obstructions in cases of multiple, peripheral, and central stenoses. This lessens the chance of inadvertent vessel perforation by passing angioplasty catheters through recently dilated vessels. Finally, it may be necessary to stage balloon dilation into separate cardiac catheterizations in individuals with bilateral multiple peripheral stenoses and those with bilateral central stenoses.

Since the results of balloon angioplasty for pulmonary arterial stenosis are not uniformly successful and long-term followup is minimal, the pediatric cardiologist has to approach the use of this procedure with some degree of caution. However, this technique has potential in the management of children with complex cardiovascular disease who otherwise might be considered inoperable. Development of techniques utilizing intravascular stents may lead to useful therapies for patients who do not respond to balloon arterioplasty.

Surgery

Surgical assistance may be attempted in patients with supravalvular pulmonary stenosis.[349] Successful relief of central obstruction in the pulmonary branches was reported initially by sev-

eral authors.[350–352] Discrete main pulmonary artery or trunk stenosis may be treated with surgery using cardiopulmonary bypass; however, the results are not entirely satisfactory.[349,353] The use of pericardial patches, woven Dacron or Gore-tex material, and tube grafts has been reported. There is no apparent prospect of surgical correction of the peripheral type of pulmonary stenosis.[313]

In our institution, the surgeon attempts relief of supravalvular or proximal pulmonary branch stenosis at the time of surgical repair of the primary congenital heart defect such as tetralogy of Fallot. If relief of obstruction is inadequate, attempts at balloon angioplasty may be made at a later date. When there is isolated pulmonary artery stenosis of significant severity, balloon angioplasty is initially performed. Surgery is reserved for cases in which the balloon dilation is unsuccessful. Transluminal balloon angioplasty appears to be the only procedure that is suitable to treat severe peripheral pulmonary arterial stenosis at this time.

ACKNOWLEDGMENT

I am particularly grateful to Geri Miller for her perseverance and technical assistance in completing this chapter.

CHAPTER 82

Aortic Arch and Pulmonary Artery Anomalies

W Robert Morrow
James C Huhta

Anomalies of the aortic arch and pulmonary arteries constitute a diverse group of malformations, ranging from the cause of life-threatening airway obstruction to as yet undescribed hypothetical anomalies. A pathologic description of an anomalous right subclavian artery exists from as early as 1735 (Hunault, cited by Moes[1]), and the first pathologic description of double aortic arch was recorded in 1737 by Hommel (cited by Moes).[1] The first report of the syndrome of vascular compression produced by a double aortic arch was published by Wolman in 1939.[2] Arkin[3] recognized the radiologic appearance of double aortic arch in 1926 with a description of the radiologic features of six cases in adults in 1936. Kommerell[4] first described the roentgenologic findings of anomalous origin of the right subclavian artery in 1936, although dysphagia had long been attributed to the retroesophageal course of this vessel. (Bayford, cited by Stewart and associates[5]). Since the introduction of accurate diagnostic methods and effective surgery,[6] the variety of reported abnormalities has increased.

The range of possible deviations from normal morphology of the aortic arch and pulmonary artery is broad. The simplest abnormalities consist of abnormal origin and course of the brachiocephalic vessels. In addition, the aorta, which normally courses to the left, may deviate to the right, with or without mirror-image branching. More complex anomalies, such as double aortic arch, involve persistence of both embryonic aortic arches with hypoplasia or atresia of segments of one or the other arch.

Vascular rings are formed when one or more aortic arch abnormalities, with or without a patent ductus arteriosus or ligamentum, produce a ring that completely encircles the trachea and esophagus leading to symptoms of tracheal or esophageal constriction. A vascular "sling," which is produced by an abnormal origin and course of the left pulmonary artery[7] or abnormal origin and course of a left ductus arteriosus,[8] does not completely encircle the trachea and esophagus but may produce symptoms of tracheal or bronchial constriction. In addition, aberrant origin of brachiocephalic vessels may rarely produce symptomatic compression of the trachea[1,9] or esophagus.[10–13]

The pathology of great vessel anomalies is best appreciated in the context of the normal embryology of the aortic arch and theoretical embryopathogenesis of aortic arch and pulmonary artery abnormalities.[5,14,15] This approach can be used to explain the great variety of aortic arch and pulmonary artery anomalies. However, not all anomalies give rise to symptoms. Indeed, some postulated abnormalities have yet to be recognized and described.[5,15] Therefore the purposes of this chapter are to explore the embryology, pathologic anatomy, and clinical consequences of anomalies of the aortic arch and pulmonary artery. We will further characterize the clinical syndromes of tracheal or esophageal compression, including symptoms, physical findings, invasive and noninvasive methods of diagnosis, natural history, indications for treatment, and surgical procedures to alleviate symptoms.

EMBRYOLOGY AND EMBRYOPATHOGENESIS

The development of the aortic arch and pulmonary arteries in the human has been described in detail by Congdon[16] and by Barry,[17] and Chapter 2 of this text gives a thorough review. A brief summary of normal great vessel embryology in the human follows.

Normal

The aortic arch initially exists as paired arteries originating from the aortic sac on the ventral surface of the embryo and coursing cephalad, then turning and pursuing a caudal and dorsal course, giving rise to the paired dorsal aorta of the embryo. As the pharyngeal pouches develop, ventral and dorsal outgrowths of the aorta fuse to form the aortic arches. The aortic arches do not all exist simultaneously but develop and regress with the development of the pharyngeal pouches. However, remnants of the aortic arches persist and contribute to important parts of the mature arterial system (Fig. 82–1). By the end of the fifth week after conception, the first and second arches have regressed. Remnants of the first arch form the primordium of the internal carotid artery and the remnants of the second arch give rise to the stapedial artery, which regresses in humans. The third pharyngeal arch persists as the common carotid artery. The left fourth arch ultimately contributes to the mature aortic arch, and the right fourth arch persists as the proximal right subclavian. The fifth aortic arch may exist in humans only in rudimentary form and therefore does not contribute to the mature arterial system. However, persistence of the fifth primitive aortic arch has been reported in humans in the form of a vascular channel parallel to the definitive aortic arch.[18–20] The distal sixth arch, which appears at the end of the fifth week, regresses on the right and persists on the left as the ductus arteriosus. Ultimately, the proximal left sixth arch contributes to the main pulmonary artery, and the proximal right sixth arch contributes to the right pulmonary artery. The distal left and right pulmonary arteries develop from the postbranchial plexus and establish connection with the proximal sixth arches to complete the vascular connection between the primitive lung and the truncus. The left dorsal aorta distal to the sixth arch and from the third through the eighth somitic segment contributes to the proximal left subclavian artery and the descending aorta distal to the left subclavian artery. On the right, the third through the seventh segment of the dorsal aorta contributes to the proximal right subclavian artery, and the eighth somitic segment normally regresses.

It is possible to describe most anomalies of the aortic arch by postulating regression of a segment of the arch that would normally persist or, conversely, persistence of a segment of the arch that would normally regress.[5,14,15] Within this theoretical framework, Edwards[14] and Stewart and associates[5] described a hypothetical double aortic arch with persistence of the aortic arch on each side and with bilateral ductus arteriosi (Fig. 82–2). The anatomy of the normal left arch and each abnormality of the aortic arch are described by persistence or regression of segments of the hypothetical double aortic arch. According to this concept, the normal left aortic arch develops by regression of the eighth segment of the right dorsal aorta. The remaining elements of the right aortic arch contribute to the development of the right brachiocephalic artery and the right subclavian artery. The right ductus arteriosus normally regresses, eliminating continuity of the sixth aortic arch on the right with the aorta.

Double Aortic Arch

Just as the development of the normal left arch may be described in terms of the hypothetical double arch, abnormalities of the aortic

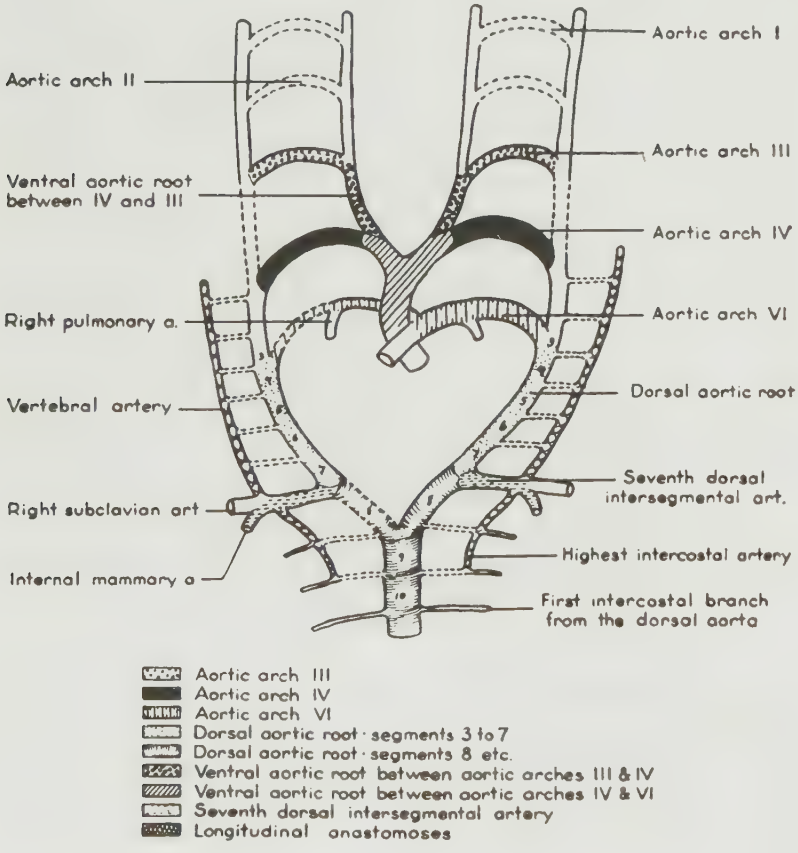

Fig. 82–1. Schematic diagram of the embryonic paired aortic arches. The aortic arches are numbered by roman numerals, and the somitic segments of the dorsal aorta are indicated by arabic numerals. Components that normally regress in the human embryo are indicated by dashed lines. (From Barry, A.: The aortic derivatives in the human adult. Anat. Rec., *111*:221, 1951.)

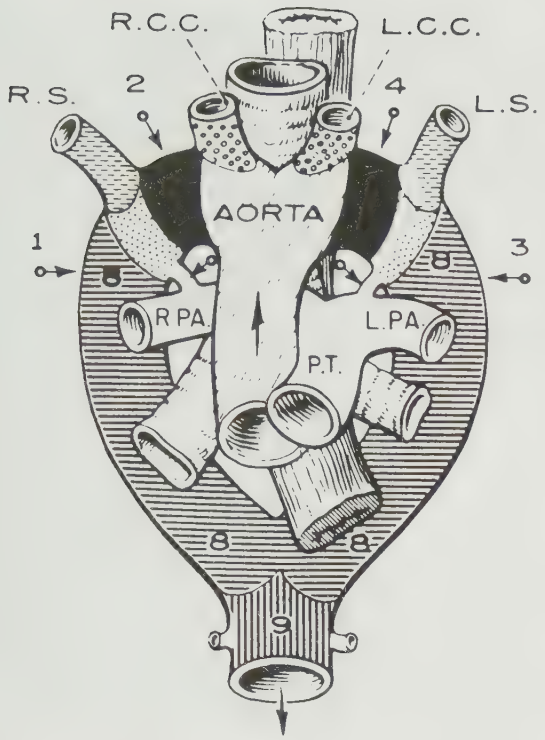

Fig. 82–2. Schematic representation of Edwards's hypothetical double aortic arch with bilateral ductus arteriosi. The ascending aorta and descending aorta are in the midline. The key to shading is that shown in Fig. 82–1. Arrows point to areas of regression, are numbered 1 through 4 for segments of the aortic arch, and are unnumbered for the ductus arteriosi. R.S. = right subclavian artery; R.C.C. = right common carotid artery; L.C.C. = left common carotid artery; L.S. = left subclavian artery; R.P.A. = right pulmonary artery; L.P.A. = left pulmonary artery; P.T. = pulmonary trunk. (From Stewart, J.R., Kincaid, O.W., and Edwards, J.E. (eds.): An Atlas of Vascular Rings and Related Malformations of the Aortic Arch System. Springfield, IL, Charles C Thomas, 1964.)

arch can also be classified by using this concept. Accordingly, double aortic arch is postulated to result from persistence of both paired dorsal aortic arches as a result of failure of regression of the right eighth somitic segment of the right dorsal aorta. The right ductus arteriosus regresses in the great majority of cases, although the ductus may persist on the right or bilaterally.[21] One or the other arch may be atretic, and atresia may theoretically occur at any segment,[5,15–17,21,22] although atresia of the segment between the ascending aorta and the left carotid has not been reported. The double aortic arch forms a complete vascular ring.[23] Persistence of the ductus arteriosus on either side is not required to complete the vascular ring in the case of double aortic arch as it is in other forms of vascular ring.

Right Aortic Arch

Right aortic arch may form by one of two mechanisms giving rise to right aortic arch with and without mirror image-branching.[5,14,15] The former occurs with abnormal regression of the left eighth dorsal aortic arch segment with persistence of the right. The ductus arteriosus almost always originates from the base of the left innominate artery. In right aortic arch without mirror-image branching, regression occurs between the left carotid and the left subclavian artery. The left subclavian artery arises from the descending aorta and courses posterior to the esophagus. In this situation, the ductus arteriosus arises from the descending aorta at the base of the left subclavian artery or from a retroesophageal diverticulum and produces a vascular ring that completely encircles the esophagus and trachea.

Anomalous Subclavian Artery

As described above, the formation of the normal left arch results from regression of the right eighth aortic arch segment. However, regression may occur between the right carotid artery and the right subclavian, giving rise to anomalous origin of the right subclavian from the descending aorta.[5,13–15] The ductus arteriosus is usually left-sided, and thus no vascular ring is formed. However, the ductus may arise from the base of the right subclavian artery or descending aorta, particularly when the descending aorta passes posterior to the esophagus and descends on the right.[24–27] This rare combination results in a vascular ring with a left aortic arch, right descending aorta, anomalous right subclavian artery, and right ductus arteriosus. A right-sided ductus arteriosus represents persistence of the distal right sixth aortic arch with regression of the distal left sixth arch.

Cervical Aortic Arch

Cervical aortic arch probably results from failure of regression of the third primitive aortic arch with regression of the contralateral arch between the carotid and subclavian arteries (fourth primitive arch).[28–30] In some cases, cervical position of the aortic arch with normal branching of the brachiocephalic arteries may merely result from failure of descent of the arch into the thorax with development.

Pulmonary Artery Anomalies

Anomalous origin of the left pulmonary artery, absent left pulmonary artery, and origin of the left pulmonary artery from the ascending aorta may all result from abnormal regression of the left proximal sixth arch. The left pulmonary postbranchial plexus, representing the vascular supply of the undivided primitive lung tissue,[16] would then establish arterial connections in one of four ways. In the case of unilateral absence of one pulmonary artery, the postbranchial plexus may establish connection to the systemic circulation by way of the distal left or right sixth arch, which would ultimately form the ductus arteriosus,[31–33] or directly to the dorsal aorta as bronchial collaterals[31] (Fig. 82–3). In some patients with origin of the right pulmonary artery from the ascending aorta, the presence of ductal tissue in the proximal right pulmonary artery implies maintenance of connection with the systemic circulation by way of the distal right sixth arch. Alternatively, origin of one pulmonary artery from the ascending aorta may result from malalignment of the conotruncal ridges.[34,35] With septation of the conotruncus, one pulmonary artery maintains connection with the ascending aorta while the other is connected to the main pulmonary artery. In patients with anomalous left pulmonary artery, arterial connection to the right pulmonary artery would occur by way of postbranchial channels between the trachea and the esophagus.[5,16,36,37] In this way, the anomalous vessel would arise from the right pulmonary artery and cross posterior to the trachea to the left hilum.

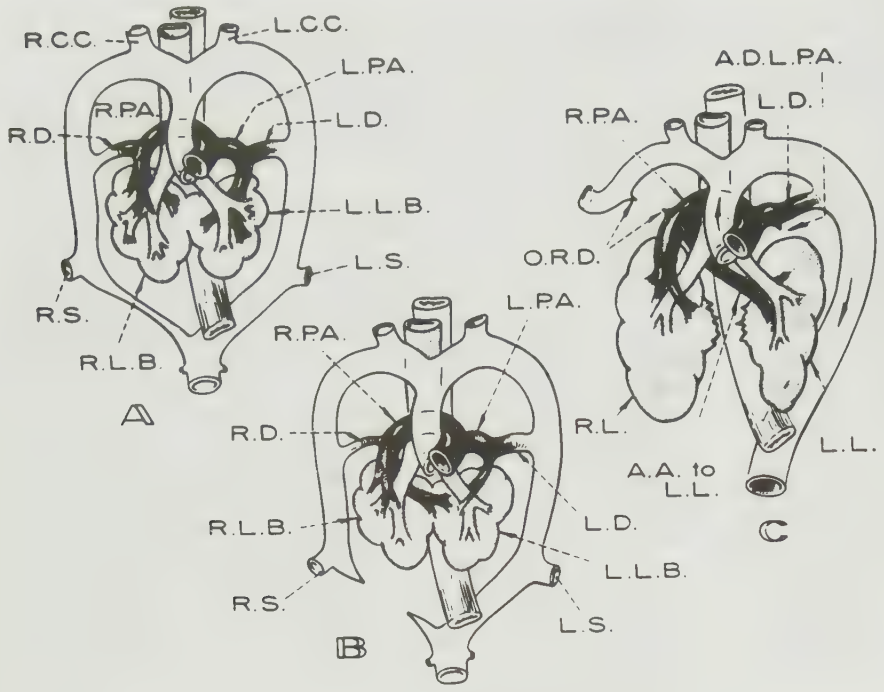

Fig. 82–3. Schematic representation of the development of the normal left pulmonary artery (A) and anomalous origin of the left pulmonary artery from the right pulmonary artery (B and C). Vessels arising from the right (R.L.B.) and left (L.L.B.) primitive lung buds normally establish connection to the proximal right (R.P.A.) and left (L.P.A.) pulmonary arteries. With anomalous origin of the left pulmonary artery from the right pulmonary artery, all or part of the vascular supply to the left lung does not establish connection to the proximal left pulmonary artery (B). Postbranchial channels persist and coalesce while maintaining connection to the right pulmonary artery (C) following division of the primitive lung buds into right lung (R.L.) and left lung (L.L.). R.D. = right ductus arteriosus; L.D. = left ductus arteriosus; O.R.D. = obliterated right ductus arteriosus; A.D.L.P.A. = atretic distal part of left pulmonary artery; R.C.C. = right carotid artery; L.C.C. = left carotid artery; R.S. = right subclavian artery; L.S. = left subclavian artery; A.A. to L.L. = anomalous artery to left lung. (From Stewart, J.R., Kincaid, O.W., and Edwards, J.E. (eds.): An Atlas of Vascular Rings and Related Malformations of the Aortic Arch System. Springfield, IL, Charles C Thomas, 1964.)

The many other possible and actual variations in aortic arch and pulmonary artery anatomy are further described by Stewart and associates[5] and by Shuford and Sybers.[15]

ETIOLOGY

Abnormalities of the aortic arch system including double aortic arch, aberrant subclavian vessels, and atresia of the sixth aortic arch have been produced in experimental animals by a number of teratogens.[38–41] Wilson[38] described the production of right aortic arch, double aortic arch, and absence of the ductus arteriosus in embryonic rats treated with azo dyes. Hodach and associates[39] produced double aortic arch by surface administration of epinephrine to chick embryos. Other catecholamines with beta-adrenergic activity also produce aortic arch anomalies when applied to the surface of chick embryos.[40] These agents also produce hypotension and tachycardia, results implying a possible hemodynamic mechanism for production of arch anomalies. The teratogenic effects of beta-adrenergic agents are potentiated by cocaine and theophylline and are attenuated by beta-adrenergic blockade.[40] Radiation exposure of mice, rat, and chick embryos in the form of roentgen rays,[42] ultraviolet light,[43] and neutron-ionizing radiation[41] also leads to the development of cardiovascular defects including aortic arch anomalies. The role of teratogenic agents in the production of aortic arch and pulmonary artery anomalies in the human is unknown.

NORMAL AND PATHOLOGIC ANATOMY

A number of classifications of aortic arch anomalies have been published.[1,5,9,15,21,44] The essential elements in any classification must include not only the side of the arch but also the origin and course of the brachiocephalic vessels, the origin of the ductus arteriosus, and the side of the descending aorta. The classifications of Stewart and associates[5] and Shuford and Sybers[15] emphasize pathologic anatomy by grouping abnormalities according to side of the aortic arch (left, right, or bilateral), origin of the brachiocephalic vessels, and site of origin of the ductus arteriosus or ligamentum arteriosus. Freedom and associates[21] have classified aortic arch and pulmonary abnormalities according to the presence or absence of vascular ring, vascular sling, or compression without formation of a vascular ring or sling. Sissman[9] has grouped abnormalities of the aortic arch by position, course, length, and size of the aorta. Each of these classifications emphasizes important aspects of anatomy and presentation of aortic arch and pulmonary artery anomalies. For the purposes of this discussion, we have adapted the classification of Stewart and associates[5] and of Shuford and Sybers[15] in describing the pathologic anatomy of aortic arch and pulmonary artery malformations. In this classification, abnormalities of the aortic arch may be divided into five groups: (1) double aortic arch, (2) right aortic arch,(3) left aortic arch with anomalous branching, (4) cervical aortic arch, and (5) pulmonary artery anomalies.

Normal Left Aortic Arch

In the simplest terms, a left aortic arch may be defined as one in which the arch courses to the left and the upper mediastinal descending thoracic aorta is to the left of the spine. Likewise, a right aortic arch could be defined as the converse of the left arch. In a normal left arch, the first branch is characteristically the right innominate artery, whereas in a left arch with anomalous branching, the right carotid artery is the first and the right subclavian artery is the last brachiocephalic artery to arise from the aortic arch and descending thoracic aorta. In a normal left arch, the aorta arises from the base of the heart to pass anterior and then to the left of the trachea. The aortic arch continues posterior and dorsal, passing to the left of the esophagus and descending in the posterior mediastinum to the left and anterior to the vertebral bodies. In the

normal left arch, the ascending aorta is the segment of the arch from the aortic valve to the origin of the innominate artery. The innominate artery arises as the first branch of the ascending aorta and passes to the right, anterior to the trachea. The innominate artery then bifurcates to form the right subclavian and carotid arteries. The second vessel to arise from the aortic arch is the left carotid. Origin of the left carotid from the innominate artery is a relatively common variation, occurring in 10 to 25% of normal patients.[45,46] When the left carotid arises from the aortic arch, the normal course of this vessel is to the left of the trachea. The third vessel arising from the aorta is the left subclavian, although the left vertebral artery may arise as the third branch in 6 to 10% of normal patients.[45,46] Distal to the origin of the left subclavian artery, the ductus arteriosus originates from the ventral surface of the descending aorta.

Double Aortic Arch

Double aortic arch is characterized by persistence of both embryonic aortic arches with separate origin of the carotid and subclavian arteries from each arch. Therefore there is no innominate artery in double aortic arch. The ascending aorta bifurcates anterior to the trachea, and each arch courses either to the left or to the right of the trachea and esophagus (Fig. 82–4). The larger of the two arches usually crosses posterior to the esophagus and joins with the other arch in the posterior mediastinum to form the unified descending aorta. Thus a complete vascular ring is formed, completely encircling the trachea and esophagus. The ductus arteriosus is almost always left sided but may originate on the right or be present on both the left and right.[5,15,21] Although the side of the ductus or ligamentum is not important in the formation of the vascular ring, the length of the ductus may affect the degree of tracheal or esophageal compression produced by the ring.

In double aortic arch, both arches are usually patent, although one arch is usually larger than the other.[5,15,22,23] When the descending aorta lies to the left of the spine, the right arch, which is more posterior than the left, is larger in approximately 70% of cases.[1,22] The right arch continues posterior to the esophagus, where it joins the left arch to continue as the descending aorta. Thus the descending aorta is usually on the left when the right aortic arch is larger. This is the most common form of double aortic arch. When the descending aorta lies to the right of the spine, the left arch is more posterior and is larger than the right in 75 to 85% of cases.[1,22] As a rule, the descending aorta is contralateral to the side of the dominant arch.

Although hypoplasia of one arch is common, segmental atresia of one arch, usually the left, occurs uncommonly.[5,15,22,23] Shuford and Sybers[15] described four subtypes of double aortic arch with segmental atresia of the left arch (Fig. 82–5). In subtype 1, atresia occurs between the left-sided ductus arteriosus and the descending

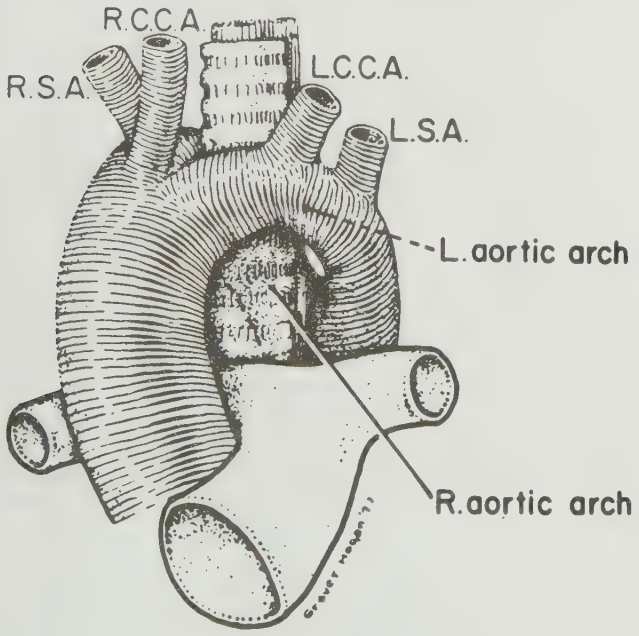

Fig. 82–4. Anatomic relationships between the trachea, esophagus, pulmonary artery, and aortic arches in double aortic arch. In this instance, the right aortic arch is larger and pursues a retroesophageal course. The vascular ring is formed by the ascending aorta anterior to the trachea, the right and left arches to either side of the trachea, and the retroesophageal right arch and descending aorta posterior to the esophagus. The ductus arteriosus or ligamentum arteriosus is not shown, since it is not an essential element of the vascular ring. R.S.A. = right subclavian artery; R.C.C.A. = right common carotid artery; L.C.C.A. = left common carotid artery; L.S.A. = left subclavian artery. (From Shuford, W.H., and Sybers, R.G.: The Aortic Arch and Its Malformations with Emphasis on the Angiographic Features. Springfield, IL, Charles C Thomas, 1974.)

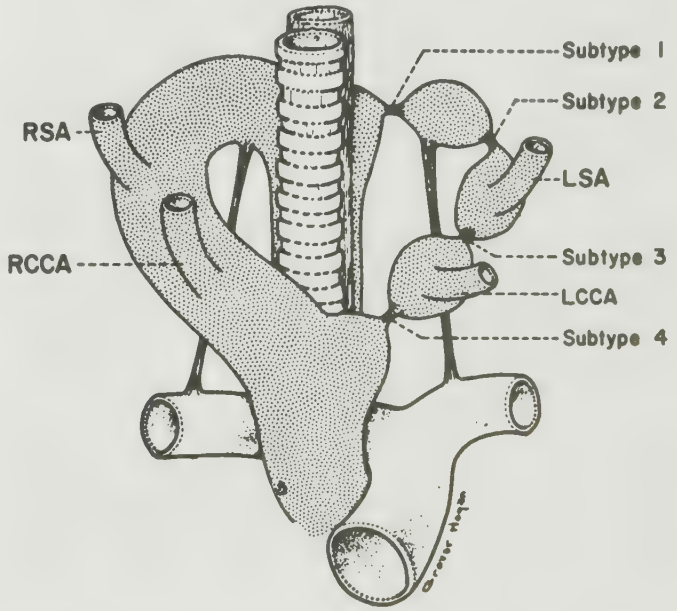

Fig. 82–5. Diagrammatic representation of double aortic arch with segmental atresia of the left arch. In subtype 1, atresia occurs between the left-sided ductus arteriosus and the descending aorta. In subtype 2, atresia occurs between the left subclavian and the left ductus arteriosus. Atresia between the left carotid artery and the left subclavian may occur (subtype 3) but is extremely rare. In subtype 4, atresia theoretically would occur between the ascending aorta and the left carotid artery but has not been reported. R.S.A. = right subclavian artery; R.C.C.A. = right common carotid artery; L.S.A. = left subclavian artery; L.C.C.A. = left common carotid artery. (From Shuford, W.H., and Sybers, R.G.: The Aortic Arch and Its Malformations with Emphasis on the Angiographic Features. Springfield, IL, Charles C Thomas, 1974.)

aorta. In subtype 2, atresia occurs between the left subclavian and the left ductus arteriosus. Subtypes 1 and 2 are rare variants of double aortic arch. Atresia between the left carotid artery and the left subclavian artery may occur (subtype 3) but is extremely rare. In subtype 4, atresia theoretically would occur between the ascending aorta and the left carotid artery. However, there has been no report of this anomaly in the literature. Double aortic arch with segmental atresia of the left arch may be difficult if not impossible to distinguish by angiography or echocardiography from various forms of right aortic arch with anomalous left subclavian artery. In addition to segmental atresia of the left arch, double aortic arch with segmental atresia of the right aortic arch has been reported.[24,25]

Double aortic arch usually occurs without associated congenital heart disease. However, associated congenital heart disease may occur in up to 22% of cases.[1] Cyanotic congenital heart disease predominates, including tetralogy of Fallot[1,5,23,47] and transposition of the great arteries.[1,48] Patients with ventricular septal defect,[1] atrial septal defect,[1,47] and true coarctation of one arch[1,5] have also been reported.

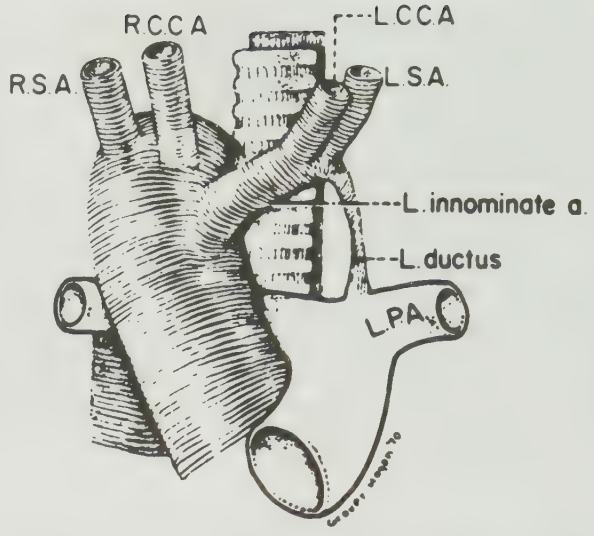

Fig. 82–6. Right aortic arch with mirror-image branching. The first branch from the ascending aorta is the left innominate artery. The ductus arteriosus typically arises from the innominate artery at the base of the left subclavian artery (L.S.A.). R.S.A. = right subclavian artery; R.C.C.A. = right common carotid artery; L.C.C.A. = left common carotid artery; L.S.A. = left subclavian artery. (From Shuford, W.H., and Sybers, R.G.: The Aortic Arch and Its Malformations with Emphasis on the Angiographic Features. Springfield, IL, Charles C Thomas, 1974.)

Right Aortic Arch

As was noted above, a right aortic arch is defined as one in which the arch courses to the right and the upper mediastinal descending thoracic aorta comes to lie to the right of the spine. Characteristically, the first branch is either the left innominate artery or the left carotid artery. Accordingly, a right aortic arch may be classified as one of two types.[49–52] In the first type, right aortic arch with mirror-image branching, the first branch of the arch is the left innominate artery. Right aortic arch with mirror-image branching of the brachiocephalic vessels is almost always associated with cyanotic congenital heart disease.

In right aortic arch with mirror-image branching, the aorta ascends anterior to the trachea and continues to the right and posterior (Fig. 82–6). The first branch is the left innominate artery, which pursues a course to the left and anterior to the trachea. The innominate artery branches to form the left subclavian artery and the left common carotid artery. The ascending aorta is often large because of the presence of associated cyanotic congenital heart disease and may originate more toward the midline than in the left aortic arch. The continuation of the arch to the right of the trachea produces deviation of the trachea to the left. The second and third branches of the arch are the right common carotid artery and the right subclavian artery, respectively. The descending aorta continues initially to the right and anterior to the vertebral bodies and then courses obliquely to the left, exiting the thorax through the aortic hiatus.

In right aortic arch with mirror-image branching, the ductus arteriosus usually arises from the left innominate artery at the origin or near the bifurcation into the carotid and subclavian. In this sense, the branching pattern of the right aortic arch is not truly a mirror image of the normal left aortic arch. However, the ductus may arise from the proximal descending aorta on the right or from a diverticulum of the descending aorta. In the latter case, the ductus arteriosus originates from a retroesophageal diverticulum (Kommerell's diverticulum) and connects to the left pulmonary artery, thus creating a vascular ring. When the ductus originates from a retroesophageal diverticulum, the descending aorta may pursue a retroesophageal course and descend on the left. In addition to left- and right-sided ductus arteriosi, cases with bilateral ductus arteriosi have been reported.[5]

In right aortic arch with anomalous origin of the left subclavian artery, there is no left innominate artery, and the first branch from the ascending aorta is the left carotid artery followed by the right common carotid artery and the right subclavian artery (Fig. 82–7). The left subclavian artery originates from the descending aorta or from a retroesophageal diverticulum of the descending aorta. In either case, a retroesophageal component is present, and the substrate for a vascular ring is present. In the great majority of cases, the ductus arteriosus is left sided and originates from the retroesophageal diverticulum and thus produces a vascular ring.[15,50] The components of the vascular ring are the ascending aorta anterior to the trachea, the right arch to the right of the trachea and esophagus, the left subclavian artery or retroesophageal diverticulum posterior to the esophagus, and the ductus arteriosus or ligamentum on the left.

As was noted above, when a retroesophageal diverticulum is present, the descending aorta may pursue a retroesophageal course and descend on the left. This condition is uncommon (25% of right aortic arch with anomalous left subclavian) and has been termed a right circumflex aorta by Hastreiter and associates.[51] Other variations in anatomy include stenosis of the left subclavian artery, isolation of the left subclavian artery, and anomalous origin of a left innominate artery.[50] Isolation of the left subclavian artery is produced by regression of the left aortic arch between the left carotid and the left subclavian and between the ductus arteriosus and the descending aorta. Thus the left subclavian may be supplied by the ductus, which is connected to the pulmonary artery. When regression occurs between the left subclavian artery and the ductus arteriosus, the left subclavian is supplied by collaterals, and the

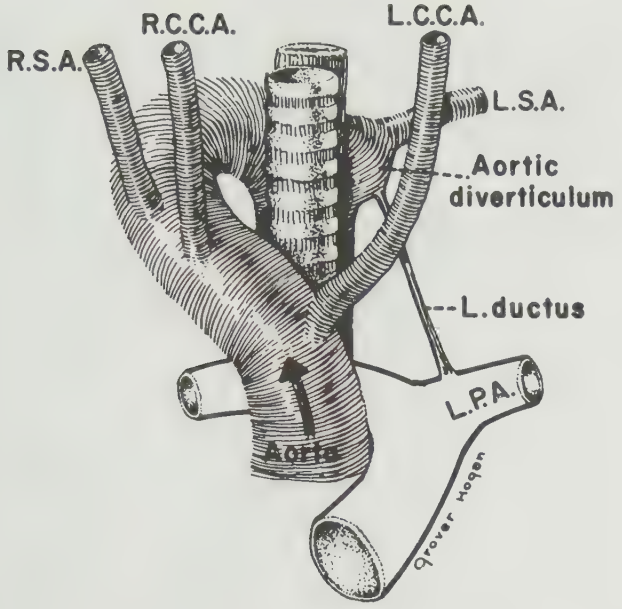

Fig. 82–7. Right aortic arch with anomalous left subclavian artery (L.S.A.) and left ductus arteriosus (L. ductus). In this illustration, the left subclavian artery and ductus arteriosus arise from a retroesophageal diverticulum (Kommerell's diverticulum) with a retroesophageal descending aorta. R.S.A. = right subclavian artery; R.C.C.A. = right common carotid artery; L.C.C.A. = left common carotid artery; L.S.A. = left subclavian artery; L.P.A. = left pulmonary artery. (From Shuford, W.H., and Sybers, R.G.: The Aortic Arch and Its Malformations with Emphasis on the Angiographic Features. Springfield, IL, Charles C Thomas, 1974.)

ductus arteriosus originates from a retroesophageal diverticulum of the descending aorta.

In right aortic arch with mirror-image branching, congenital heart disease, usually cyanotic, is present in up to 98% of patients, whereas with anomalous origin of the left subclavian, associated congenital heart disease is uncommon.[49] In tetralogy of Fallot, from 13 to 34% of patients have right aortic arch.[1,21,49,51,52] Of these, 93% have right aortic arch with mirror-image branching.[49] Likewise, the incidence of right aortic arch is relatively high in truncus arteriosus (36%)[1,21,49,51] and double outlet right ventricle (20%).[21] Right aortic arch is seen infrequently in transposition of the great arteries, being present in only 3% of cases. When present in transposition, right arch is most often associated with ventricular septal defect and pulmonary valve stenosis or single ventricle with or without pulmonary valve stenosis.[21,49] Right aortic arch may also be found in patients with tricuspid atresia (5 to 8%), ventricular septal defects (2 to 6%), and ventricular inversion with transposition (1%).[21,49,51] According to Nath and associates,[53] although congenital heart disease is uncommon, when it is present in association with right aortic arch and an anomalous left subclavian, the upper descending aorta is usually on the right, that is, there is no retroesophageal segment of the aorta. When the descending aorta takes a retroesophageal course to the left, associated congenital heart disease is unlikely.

Left Aortic Arch with Anomalous Branching

Abnormalities of origin and course of the brachiocephalic vessels may be seen in patients with a left aortic arch. Anomalous origin of the right subclavian artery from the descending aorta is the most common anomaly of the aortic arch, being present in autopsy series in 0.5% of cases.[5,12,54] The anatomy of the aortic arch is normal with the exception of origin of the right subclavian artery from the descending aorta as the last branch (Fig. 82–8). This is presumed to occur as a result of regression of the right fourth primitive aortic arch between the right common carotid artery and the right subclavian artery. The right subclavian artery originates from the descending aorta at the level of the fourth thoracic vertebra and crosses the midline posterior to the esophagus. Reports of the anomalous right subclavian artery crossing the midline between the esophagus and the trachea have been disputed.[12,13] As in right aortic arch with anomalous left subclavian artery, an anomalous right subclavian artery may also originate from a retroesophageal diverticulum termed "Kommerell's diverticulum."[4] The descending aorta usually continues to the left and anterior to the thoracic vertebral bodies. When the ductus arteriosus is left sided, as it is in most cases, there is no vascular ring. However, the ductus arteriosus may arise from the Kommerell's diverticulum and connect to the right pulmonary artery. This is usually seen in association with left aortic arch and right descending aorta and is analogous to right aortic arch with circumflex left descend.[24,26,27] This rare combination of left aortic

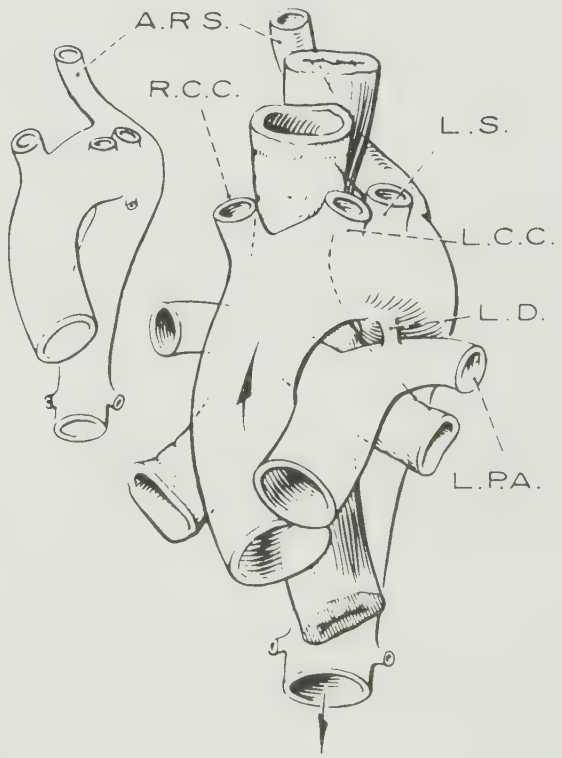

Fig. 82–8. Anomalous origin of the right subclavian artery (A.R.S.) from the descending aorta. The first branch of the ascending aorta is the right common carotid artery (R.C.C.) and the right subclavian artery arises as the last branch. Both the aortic arch and the descending aorta are on the left. L.S. = left subclavian artery; L.C.C. = left common carotid artery; L.D. = left ductus; L.P.A. = left pulmonary artery. (From Stewart, J.R., Kincaid, O.W., and Edwards, J.E. (eds.): An Atlas of Vascular Rings and Related Malformations of the Aortic Arch System. Springfield, IL, Charles C Thomas, 1964.)

arch, anomalous right subclavian artery, right ductus arteriosus, and right descending aorta produces a vascular ring.

Anomalous origin of the right subclavian artery with left arch is usually an isolated anomaly. Associations with various congenital heart defects including tetralogy of Fallot, ventricular septal defect, patent ductus arteriosus, and coarctation of the aorta have been reported.[1] In coarctation, the origin of the anomalous right subclavian artery is usually distal to the site of coarctation, which may lead to reduced blood pressure in the right arm as well as the legs. In tetralogy of Fallot, anomalous origin of the right subclavian artery has a major effect on the choice of systemic-to-pulmonary shunt performed for palliation of cyanosis. In addition, anomalous right subclavian artery has been reported to occur in 38% of patients with trisomy 21 and congenital heart disease and may be more common in trisomy 21 without congenital heart disease.[55]

The common variants in origin of the brachiocephalic vessels in left aortic arch have been noted above. These include origin of the left common carotid artery from the innominate artery and separate origin of the left vertebral artery from the aortic arch. Tracheal compression has been attributed to anomalous origin and course of the innominate artery,[1,56–62] although the role of this anomaly in producing symptoms is disputed,[63,64] and a conservative approach to diagnosis and treatment has been advocated.[65,66] Anterior indentation of the trachea is frequently noted in children without symptoms compatible with obstruction caused by an anomalous innominate artery,[67] with more severe compression in infants with tracheoesophageal fistula and in the presence of diffuse or localized tracheomalacia.[58–60,64–67] The branching pattern of the aorta is normal in patients with anomalous innominate artery. A distal origin of the innominate artery to the left of the trachea has been cited as a possible mechanism for production of symptoms of tracheal compression.[58] However, Cohen[64] found normal origin of the innominate artery in all patients undergoing surgery for airway obstruction with anterior indentation of the trachea by the innominate artery and with coexisting localized or diffuse tracheomalacia.

Cervical Aortic Arch

Cervical aortic arch is an uncommon abnormality of aortic arch development. The essential anatomy of cervical arch has been described[28] and includes (1) cervical position of the aortic arch, (2) separate origin of the carotid artery contralateral to the side of the aortic arch with anomalous origin of the subclavian artery contralateral to the aortic arch, and (3) retroesophageal descending thoracic aorta. Haughton and associates[68] have offered a somewhat expanded classification of cervical aortic arch in which the only common feature among the five types is cervical position of the aorta. In this classification, there are basically two major types: those with a contralateral descending aorta and those with an ipsilateral descending aorta. Those with a contralateral descending aorta are further subdivided into groups according to the origin and branching pattern of the carotid arteries. Those with an ipsilateral aortic arch are further divided into those with a left arch and normal branching and those with a right arch and anomalous left subclavian artery from the descending aorta.

In patients with cervical aortic arch, the ascending aorta arises from the left ventricle and ascends into the neck, usually on the right[28] (Fig. 82–9). Although less frequent, the apex of the arch may be on the left.[69–72] The arch may be as high as the second cervical vertebra[9] but usually lies at or below the third through the eighth cervical vertebrae.[1] The branching pattern of the brachiocephalic vessels is variable with separate origin of the internal and external carotid arteries on one or both sides or with a bicarotid trunk.[15,28,72] The subclavian artery on the side of the arch arises near the apex of the arch. The descending aorta enters the thorax on the side of the arch and crosses the midline posterior to the esophagus at the level of the fourth thoracic vertebral body. The subclavian artery contralateral to the arch arises from the descending aorta either directly or from a diverticulum of the descending aorta after the aorta crosses the midline. In addition, the origin of the contralateral subclavian is often stenotic, particularly when arising from a Kommerrell's diverticulum. The position of the ductus arteriosus is variable. If the ductus arteriosus arises from the descending aorta contralateral to the side of the arch, a vascular ring is formed. Associated congenital heart disease is rare, although aortic obstruction due to redundancy of the aorta has been observed.

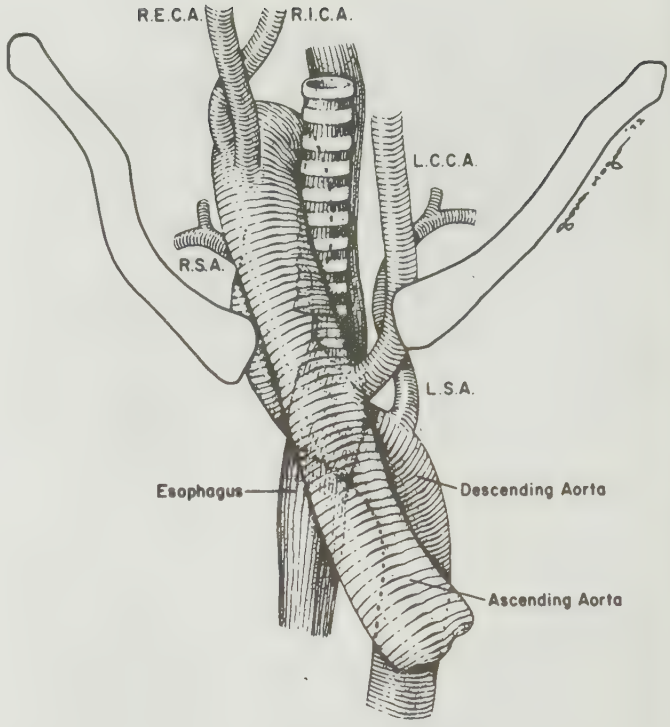

Fig. 82–9. Cervical aortic arch. The arch ascends on the right into the cervical region, then re-enters the thorax on the right. The descending aorta pursues a retroesophageal course. The right internal carotid artery (R.I.C.A.) and right external carotid artery (R.E.C.A.) have separate origins, and the left subclavian artery (L.S.A.) originates from the descending aorta. L.C.C.A. = left common carotid artery; R.S.A. = right subclavian artery. (From Shuford, W.H., and Sybers, R.G.: The Aortic Arch and Its Malformations with Emphasis on the Angiographic Features. Springfield, IL, Charles C Thomas, 1974.)

Essentially, two theories have been advanced to account for the pathologic anatomy of cervical aortic arch. Abnormal persistence of the second or third primitive aortic arch has been postulated to account for cervical position of the arch and the abnormal origin and branching of the carotid arteries.[15,28] This hypothesis would

account for separate origin of the internal and external carotid arteries as well as the cervical position of the apex of the aortic arch. An alternative hypothesis is that the cervical position of the aortic arch merely represents failure of the arch to descend into the thorax during fetal development. However, the separate origin of the internal and external carotid arteries and the anomalous origin of the contralateral subclavian artery are most easily explained by persistence of the primitive third arch on the side of the aortic arch with regression of the primitive fourth arch on the contralateral side. It is possible that abnormal persistence of the third primitive aortic arch accounts for the more common form of cervical aortic arch with abnormal origin and branching of the brachiocephalic arteries, whereas failure of descent of the aortic arch accounts for those cases with an ipsilateral descending aorta. The patient reported by Cornali and associates[29] is interesting in considering the embryopathogenesis of cervical aortic arch. In this case, where there was double aortic arch with a left cervical arch on one side and a right thoracic arch on the other, it is difficult to postulate failure of descent of the left cervical arch with coexistence of a right aortic arch in the thorax. It is more likely that the left cervical arch developed as a result of persistence of the left third aortic arch and the right arch resulted from persistence of the right eighth somitic segment of the dorsal aorta. However, although it is interesting to speculate on the embryopathogenesis of cervical aortic arch, such speculation has little bearing on the recognition and management of this rare anomaly.

Pulmonary Artery Anomalies

In addition to abnormalities of the definitive aortic arch, abnormal origin and course of the branch pulmonary arteries probably result from abnormal persistence or regression of components of the primitive aortic arch system, specifically the primitive sixth aortic arches. The pathology of anomalous origin of the left pulmonary artery, absence of a single pulmonary artery, and origin of a single pulmonary artery from the ascending aorta will be described below.

Anomalous Origin of the Left Pulmonary Artery

In addition to anomalies of the aortic arch, anomalous origin of the left pulmonary artery may produce tracheal compression by creating a "vascular sling."[7] The left pulmonary artery arises from the posterior surface of the right pulmonary artery, passes over the right main stem bronchus, then crosses the midline posterior to the lower trachea or carina and anterior to the esophagus[5,36,73] (Fig. 82–10). The anomalous left pulmonary artery then enters the hilum of the left lung and divides. The anomalous left pulmonary artery characteristically enters the left hilum at a lower level than normal. Therefore in contrast to aortic arch anomalies that produce vascular rings, the compression produced by the anomalous left pulmonary artery is on the posterior surface of the trachea and does not completely encircle the trachea and esophagus. The ductus arteriosus is left sided and connects to the main pulmonary artery.

Atresia or agenesis of the proximal left sixth arch has been postulated as the cause of this anomaly. Establishment of collateral blood flow through the postbranchial plexus to the left lung eventually results in the formation of an anomalous left pulmonary artery with connection to the right pulmonary artery. This hypothesis is supported by the finding of mixed pulmonary arterial

Fig. 82–10. Schematic representation of anomalous origin of the left pulmonary artery. The anomalous left pulmonary artery originates from the posterior superior surface of the right pulmonary artery and crosses between the trachea and esophagus in its course to the left hilum. This produces a "sling," which leads to compression of the right main stem bronchus and the lower trachea. R.C.C. = right common carotid artery; L.S. = left subclavian artery; R.S. = right subclavian artery; L.C.C. = left common carotid artery; R.P.A. = right pulmonary artery; P.T. = pulmonary trunk. (From Stewart, J.R., Kincaid, O.W., and Edwards, J.E. (eds.): An Atlas of Vascular Rings and Related Malformations of the Aortic Arch System. Springfield, IL, Charles C Thomas, 1964.)

supply to the right and left lungs, in some cases with anomalous left pulmonary artery. In one case, the arterial supply to the right upper lobe was provided by the anomalous left pulmonary artery.[74] In another case, arterial supply to the left upper lobe was provided by a left pulmonary artery in the normal position, whereas the arterial supply to the left lower lobe was provided by an anomalous left pulmonary artery.[37]

Associated congenital anomalies are common, being present in 58 to 83% of patients.[73] Approximately 40 to 50% of patients have associated congenital heart disease.[73,75–77] Persistent left superior vena cava, atrial septal defect, and patent ductus arteriosus are commonly present. An associated ventricular septal defect may be present in up to 10% of patients. Other cardiac defects that may be associated with anomalous left pulmonary artery include

tetralogy of Fallot, atrioventricular canal, common ventricle, coarctation, transposition of the great arteries, and scimitar syndrome.[76–78]

In addition to associated cardiac defects, malformations of the trachea frequently coexist with anomalous left pulmonary artery. These malformations include complete cartilaginous rings (absence of the pars membranacea), tracheomalacia, abnormal pulmonary lobulation, and bronchus suis.[73,76–78,79] Complete cartilaginous rings with absence of the pars membranacea may affect up to 50% of patients. In addition to complete rings, there is variation in number and distribution of tracheal rings.[79] The tracheal abnormalities persist after surgery and contribute significantly to the high morbidity and mortality rate in affected patients both before and after surgical repair of the anomalous left pulmonary artery. It appears that the tracheal abnormalities are primary, although some degree of deformation of the trachea may be secondary to compression by the anomalous left pulmonary artery. This is supported by the association of other primary malformations including imperforate anus, Hirschsprung's disease, biliary atresia, genitourinary defects, and anomalies of other organ systems.[73,76,77]

As was noted above, anomalous origin of the left pulmonary artery probably results from atresia of the proximal left sixth arch or failure of connection of the postbranchial plexus with the proximal left sixth arch. The anomalous left pulmonary artery would then form from postbranchial channels between the trachea and esophagus and thereby maintain connection to the right pulmonary artery[5,36,37] (Fig. 82–10). In this way, the anomalous vessel would arise from the right pulmonary artery and cross posterior to the trachea to the left hilum.

Unilateral Absence of One Pulmonary Artery

Unilateral absence of one pulmonary artery, first described by Fraentzel in 1868 (cited by Pool and associates[31]), is an uncommon congenital defect. Of 78 cases reviewed by Pool and associates,[31] 40% occurred without other associated cardiac defects. Of the remaining patients, those with absent left pulmonary artery usually had associated tetralogy of Fallot, whereas those with absence of the right pulmonary artery usually had associated patent ductus arteriosus (to the normally connected pulmonary artery). The absent pulmonary artery is usually opposite the side of the aortic arch. Ventricular septal defects are not uncommonly observed.[31] In addition, patients with atrial septal defects, patent ductus arteriosus, aortopulmonary window, subaortic stenosis with coarctation, transposition, aberrant left subclavian artery, and truncus arteriosus have been reported.[31,33]

Although the proximal pulmonary artery is absent on the affected side, the distal pulmonary artery can often be identified at surgery.[32] Thus the term "occult pulmonary artery" as suggested by Presbitero and associates[32] may be more appropriate. This vessel, which may be intrapericardial or extrapericardial, enters the hilum of the affected lung and arborizes in a way similar to a normal pulmonary artery. The arterial supply to the occult pulmonary artery may be by way of a ductus arteriosus, particularly when the affected pulmonary artery is extrapericardial, or by way of systemic collaterals. The latter may develop following ductal constriction. The contribution of bronchial circulation to arterial supply of the affected lung increases with age.[9] Evidence of initial supply to the affected pulmonary artery by the ductus arteriosus is present in the majority of cases in which the occult pulmonary artery is on the side opposite the aortic arch.[31,33]

Origin of One Pulmonary Artery from the Ascending Aorta

Origin of one pulmonary artery from the ascending aorta is a rare anomaly, occurring in 0.05% of patients with congenital heart disease.[80] Unlike truncus arteriosus, in unilateral origin of a branch pulmonary artery from the ascending aorta, there are separate pulmonary and aortic valves, and thus the term "hemitruncus" is misleading. In approximately 88% of patients, the right pulmonary artery arises from the ascending aorta and is usually the same size as, or larger than, the left pulmonary artery. Rarely, there may be stenosis at the origin of the right pulmonary artery. The vessel connects to the aorta just above the aortic valve and on the right or posterior and courses directly to the right hilum.

Overall, 75% of patients with origin of one pulmonary artery from the ascending aorta have a patent ductus arteriosus.[80] When the right pulmonary artery arises from the ascending aorta, 50% have an associated patent ductus arteriosus.[81,82] Other cardiac defects associated with origin of the right pulmonary artery from the ascending aorta include ventricular septal defect, aortopulmonary window, coarctation of the aorta, interrupted aortic arch, atrial septal defect, tetralogy of Fallot,[78,80,83,84] and contralateral pulmonary vein stenosis.[78]

Origin of the left pulmonary artery from the ascending aorta occurs as an isolated anomaly in approximately 40% of patients. In these, the aortic arch is usually on the right. In patients with associated congenital heart disease, tetralogy of Fallot is often present and is usually accompanied by a left aortic arch.[81,83,84] Patients with tetralogy of Fallot may also have severe hypoplasia of the normally connected pulmonary artery[84] or absent pulmonary valve syndrome.[81] Beitzke and Shinebourne[85] reported an unusual patient with origin of both the right and left pulmonary arteries from the ascending aorta. The main pulmonary artery did not branch and was connected to the descending aorta by a patent ductus arteriosus.

Anomalous origin of a pulmonary artery from the ascending aorta may occur as a result of abnormal conotruncal septation[34,35] or secondary to regression of the proximal right sixth arch with persistent connection of the distal right sixth arch to the aorta.[5] The former hypothesis is more plausible, since the ductus would be expected to connect the anomalous vessel to the distal aortic arch and not the ascending aorta if the distal sixth arch persisted. In addition, ductal tissue is rarely observed in the anomalously connected right pulmonary artery.

Summary of Pathology of Vascular Rings

In summary, tracheal and esophageal compression can be produced by many different variations in anatomy of the aortic arch and pulmonary artery. A complete vascular ring is formed when the trachea and esophagus are completely encircled by derivatives of the aortic arch. This always occurs in double aortic arch irrespective of the site of origin of the ductus arteriosus. Attachment of the ductus arteriosus to the pulmonary artery on the side opposite the aortic arch is always present in other forms of vascular ring. In right aortic arch with anomalous origin of the left subclavian artery, a vascular ring is almost always present and is completed by a left-sided ductus arteriosus arising from the descending aorta. Rarely, a vascular ring may exist in the presence of a left aortic

arch with anomalous origin of the right subclavian artery and with a right ductus arteriosus originating from the retroesophageal right descending aorta. Posterior esophageal compression occurs in cervical aortic arch because of the retroesophageal course of the aorta and, if the ductus is contralateral to the side of the cervical arch and ipsilateral to the descending aorta, because of a coexisting vascular ring. Tracheal and esophageal compression may be produced by origin of the left pulmonary artery from the right pulmonary artery or by connection of a left-sided ductus arteriosus to the right pulmonary artery. This has been termed a "vascular sling"[7] because, unlike vascular rings, the trachea and esophagus are not completely encircled. In both anomalous left pulmonary artery and ductus arteriosus sling, the anomalous vessel courses between the esophagus and the trachea, producing posterior and lateral tracheal compression and anterior esophageal compression.

DIAGNOSTIC EVALUATION

Aortic arch and pulmonary artery anomalies may produce life-threatening symptoms or may be asymptomatic. Symptomatic vascular rings are relatively uncommon; in addition, the symptoms of vascular compression produced by these defects are nonspecific. All too often, vascular anomalies are initially overlooked in infants with acute or chronic airway obstruction. However, a variety of noninvasive and invasive methods are available for accurate diagnosis of aortic arch and pulmonary artery anomalies. In this section, the approach to diagnosis of aortic arch and pulmonary artery malformations will be discussed and will include a review of symptoms and signs, radiologic evaluation, echocardiographic evaluation, and angiography.

Symptoms and Signs

Anomalies of the aortic arch and pulmonary artery may present with a wide range of clinical manifestations. In most intances, an abnormal course of the aorta or origin of brachiocephalic vessels is an incidental finding on chest radiographs or in the course of evaluation for suspected congenital heart disease. Difficulty in swallowing was at one time liberally attributed to anomalous origin of the right subclavian artery (dysphagia lusoria) with a retroesophageal course.[13,57,86] Although a retroesophageal right subclavian artery may very occasionally produce dysphagia,[10,11] this abnormality is clearly asymptomatic in the great majority of individuals.[12]

The most significant symptom that may occur with vascular ring is respiratory distress in the form of stridor, dyspnea, cough, and occasionally wheezing.[1,14,15,47,56] The great majority of infants and children with stridor do not have vascular rings or vascular slings as the cause of their respiratory distress.[87,88] More common causes of chronic stridor include tracheomalacia, laryngomalacia, subglottic stenosis, subglottic hemangioma, tracheal web, and foreign bodies, among many others. However, stridor and dyspnea with aortic arch and pulmonary artery anomalies may be very severe, particularly with double aortic arch or pulmonary artery sling. The severity of symptoms and the age of onset of respiratory distress are primarily determined by the degree of constriction of the trachea produced by the abnormal course of the aortic arch or pulmonary artery. Thus presentation at an early age with severe symptoms is likely with double aortic arch and pulmonary artery sling, whereas later presentation and milder symptoms are the rule with right aortic arch with an anomalous left subclavian and left ductus arteriosus. In reality, vascular rings produced by right aortic arch and anomalous left subclavian artery and left ductus arteriosus are asymptomatic in the great majority of individuals.[49] Difficulty in swallowing solid foods, or dysphagia, may be encountered in older infants and children with vascular rings.

The occurrence of sudden episodes of apnea with cyanosis in patients with tracheal compression has been termed "reflex apnea."[62] These episodes can ultimately lead to death; Fearon and Shortreed[62] and others[64] have concluded that apneic episodes should lead to early surgical intervention. However, it is important to exclude other causes of apnea in affected infants, particularly those with lesions that usually do not produce significant tracheal compression, to avoid unnecessary thoracotomy.

Findings on physical examination of symptomatic infants are those of severe respiratory distress and do not otherwise suggest the presence of a vascular anomaly. Additional physical findings may be present in patients with associated congenital heart disease. These are specific for the associated defect, such as cyanosis in tetralogy of Fallot, and do not ordinarily imply the existence of vascular anomalies. However, in coarctation of the aorta, a reduced right arm pulse in addition to reduction in leg pulses suggests the presence of an anomalous right subclavian artery arising below the site of coarctation. Since the left subclavian artery can occasionally be stenotic in coarctation, it is possible to have low-volume pulse in all extremities, making routine carotid palpation a necessity. Likewise, a pulsatile mass in the neck with a thrill and systolic murmur clearly suggests the possibility of a cervical aortic arch. Loss of femoral artery pulses on compression of the mass is pathognomonic of cervical aortic arch.[28]

Radiologic Examination

For many years, chest radiography and esophagography have been the primary diagnostic modalities used to confirm or exclude aortic arch anomalies in patients with a compatible history.[5,15,46,49,89] The anteroposterior chest radiograph is most useful in determining the laterality of the aorta. In addition to demonstrating the side of the aortic arch, the course of the descending aorta can usually be determined. In left aortic arch, the density of the aortic arch can be seen to the left of the trachea and produces rightward deviation of the trachea as the arch passes to the left and posterior. This deviation of the trachea can be identified in most patients, although tracheal deviation may be obscured by generous thymic tissue in infants. Nonetheless, deviation of the trachea to the right usually implies the existence of a left aortic arch, whereas tracheal deviation to the left is the rule in right aortic arch (Fig. 82–11). In the normal left aortic arch, the oblique course of the descending aorta along the left margin of the vertebral bodies identifies the descending aorta as left descending. In right aortic arch or left aortic arch, the descending aorta may be seen to cross to the contralateral side and thus represents a "circumflex aorta," and a vascular ring may be present.

Cases of double aortic arch with dominant left arch may have tracheal deviation to the right without other evidence of the right arch on chest radiography. However, abnormal tracheal deviation in double aortic arch may not be apparent because of generous thymic shadows. In addition, frank tracheal constriction may be recognized in double aortic arch by narrowing or obliteration of the distal tracheal air column (Fig. 82–12). A descending aorta

Fig. 82–11. Anteroposterior chest radiograph of a patient with right aortic arch and anomalous left subclavian artery. The aortic arch produces deviation of the trachea to the left. The side of the descending aorta cannot be clearly identified in this radiograph.

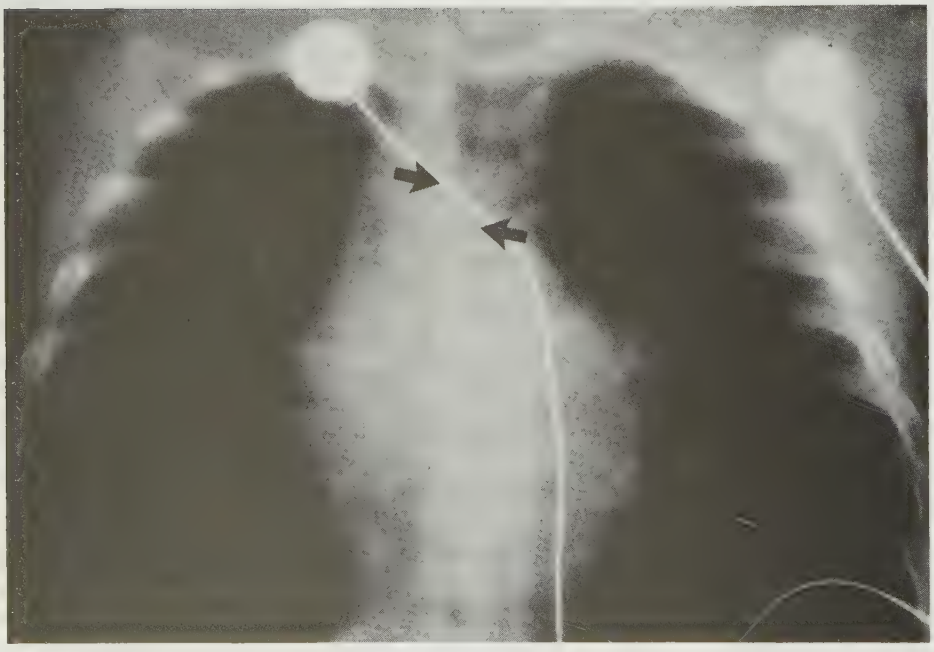

Fig. 82–12. Anteroposterior chest radiograph of a one-month-old patient with severe respiratory distress and double aortic arch. Note the bilateral hyperinflation in addition to severe constriction of the trachea on both the right and the left (arrows).

contralateral to the side of the dominant aortic arch is usually seen in double aortic arch.

Other inferences as to the type of aortic arch anomaly may be made on the basis of the presence of aortic enlargement, an abnormal cardiac silhouette, or reduced pulmonary vascular markings. In patients with cyanotic congenital heart disease, the right aortic arch is likely to have a mirror-image branching pattern, and a vascular ring is very unlikely. Likewise, a right aortic arch without findings compatible with congenital heart disease is likely to have an anomalous left subclavian artery, and the substrate for a vascular ring exists. With pulmonary artery sling, the chest radiograph shows hyperinflation on the right, the left, or bilaterally secondary to main stem bronchus obstruction. If obstruction is severe, atelectasis may be seen, particularly on the right.

Although sometimes useful, lateral chest radiographs may be normal in the presence of significant abnormalities of the aortic arch or pulmonary arteries. Anterior tracheal indentation has been noted in some patients with anomalous innominate artery,[58,59,62] although Swischuk[63] has emphasized that anterior tracheal indentation is commonly observed in normal children on lateral chest radiographs.

Although chest radiography may provide useful information in patients with suspected aortic arch anomalies, the mainstay of noninvasive diagnosis has been barium esophagography.[5,15,46,49,89] A comprehensive review of findings on esophagography has been provided by Stewart and associates,[5] Shuford and Sybers,[15] and Neuhauser.[44] The barium study should be interpreted from fluoroscopy or cine films. Both anteroposterior and lateral views are useful in describing abnormalities that may be present. In anteroposterior views, the oblique course of an anomalous left or right subclavian can be seen as the anomalous artery indents the barium-filled esophagus (Fig. 82–13). Bilateral indentations of the esophagus are often seen in double aortic arch in the anteroposterior projection, the larger arch producing a deeper, more superior indentation (Fig. 82–14). Berdon[89] has divided findings on lateral esophagography into four patterns. A large posterior indentation of the barium-filled esophagus with anterior tracheal indentation is seen in double aortic arch and right or left aortic arch with a retroesophageal descending aorta, anomalous subclavian, and a ductus arteriosus contralateral to the side of the aortic arch (Fig. 82–14 and Fig. 82–15). A shallow posterior indentation is produced by an anomalous subclavian artery without a ductus arteriosus contralateral to the arch (Fig. 82–13). Anterior indentation of the trachea or straightening of the trachea is not seen in this group, since the ductus is on the side of the arch and there is no vascular ring with compression. As was noted above, anterior tracheal indentation may be seen with innominate artery compression of the trachea. In these patients, barium esophagography is normal. The last group consists of patients with pulmonary artery sling with anterior indentation of the esophagus. In most instances, with a combination of plain chest radiography and esophagography, the type of vascular anomaly can be established. However, confusion can exist when findings are not characteristic, and conventional angiography or digital angiography should be performed when surgery is contemplated.

Echocardiographic Examination

Two-dimensional echocardiography has become a useful noninvasive method both to establish the laterality of the aortic arch and descending aorta and to determine the origin of the brachiocephalic vessels from the aorta.[90–94] In addition, normal bifurcation of the main pulmonary artery into left and right pulmonary arteries is usually easily demonstrated by two-dimensional echocardiography, effectively excluding pulmonary artery sling or absence of either branch pulmonary arteries or anomalous origin of one pulmonary artery from the ascending aorta.[84,90,95–97] The echocardiographic diagnosis of the majority of abnormalities of the aortic arch and pulmonary artery that would produce a vascular ring depends on demonstrating either absence of a normal right innominate artery or abnormal origin of the left pulmonary artery or ductus arteriosus ligamentum.

Accurate demonstration of aortic laterality and branching of the

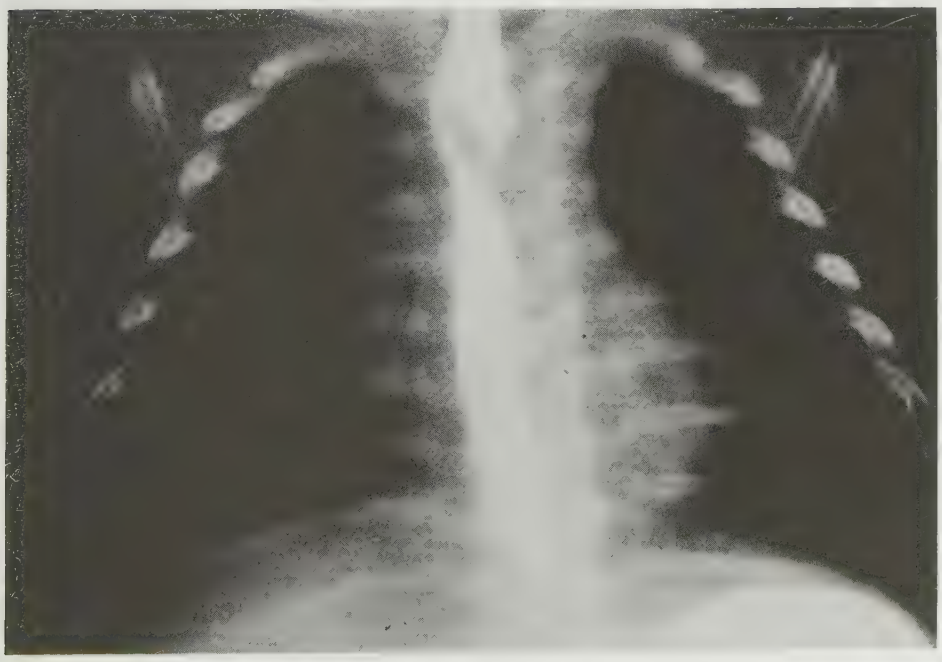

Fig. 82–13. Typical findings on barium esophagography in a patient with tetralogy of Fallot, left aortic arch, and anomalous right subclavian artery. In the anteroposterior projection, the retroesophageal right subclavian artery produces an oblique defect from left inferior to right superior.

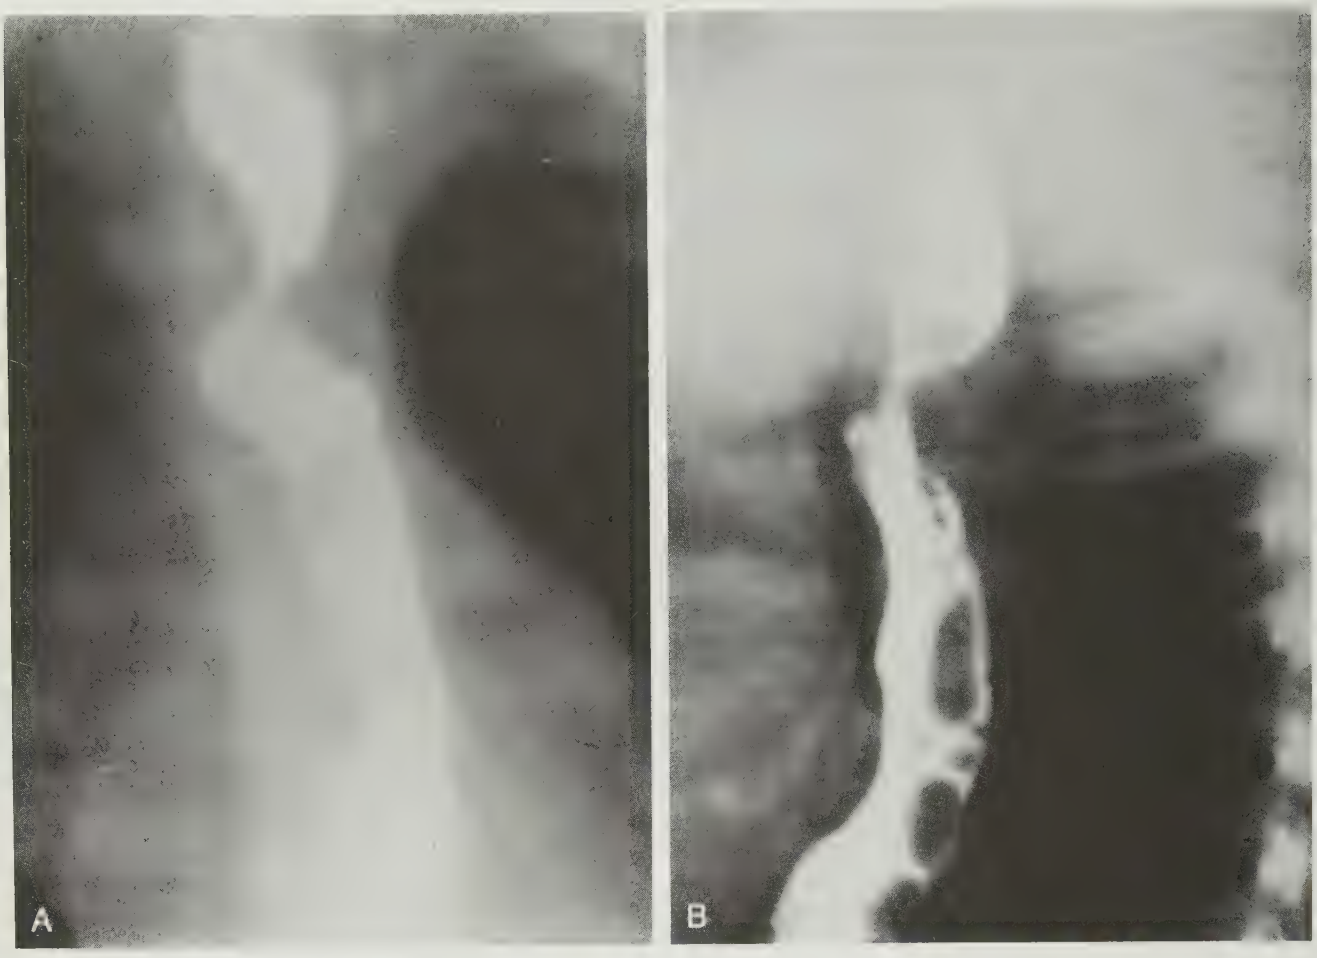

Fig. 82–14. The classic appearance of double aortic arch on barium esophagography in the anteroposterior projection is illustrated in part A. The double arch produces bilateral indentations on the upper esophagus. In part B, near-complete obstruction of the esophagus is produced by posterior compression of the esophagus by the retroesophageal portion of the arch.

aorta can be obtained only by employing a segmental approach to examination of the aortic arch as described by Huhta.[90] In this method, the ascending aorta is visualized from the suprasternal notch in a coronal plane. By directing the transducer to the right with clockwise rotation, the origin of the right innominate artery as the first branch of the ascending aorta identifies the arch as a left arch (Fig. 82–16). Normal branching of the right innominate artery excludes anomalous origin of the right subclavian artery. Clockwise rotation of the transducer and scanning to the left and posterior bring the transverse arch with the origin of the left carotid artery and left subclavian artery into view. From a high left parasternal position, scanning in the sagittal plane identifies the descending aorta to the left of the esophagus and trachea. Visualization of the esophagus may be aided by having the patient swallow a carbonated beverage or infant formula. The examination is completed by scanning from a subcostal position with visualization of the descending aorta on the left.

In right aortic arch, the first vessel to arise from the aorta courses to the left and is identified by counterclockwise rotation of the transducer. If this vessel branches to form a left subclavian artery and a left carotid artery, then mirror-image branching is present (Fig. 82–17). Scanning to the right reveals the descending aorta. Right aortic arch with mirror-image branching can be identified correctly in most patients by demonstrating a left innominate artery that branches to form a left carotid and a left subclavian with a descending aorta that courses to the right of the trachea.[90,91] However, if branching of the left innominate artery does not occur, then an anomalous left subclavian artery should be suspected, and the substrate exists for a vascular ring (Fig. 82–18). With careful examination, the anomalous left subclavian artery can be demonstrated arising from the descending aorta or from a diverticulum of the descending aorta in many cases. When patent, the left-sided ductus arteriosus can be visualized or demonstrated by pulsed Doppler sampling in the pulmonary artery (Fig. 82–19). Correct identification of vascular ring resulting from a right aortic arch with an anomalous left subclavian artery and left ductus arteriosus has been reported.[90,94] In double aortic arch with both arches patent, a characteristic coronal scan from the suprasternal notch is produced.[90,91,93] The dominant arch can often be identified, and the course of each arch can be established (Fig. 82–20).

Accurate diagnosis of anomalous left pulmonary artery can be made by scanning from both suprasternal notch and parasternal short-axis views and from the subxiphoid view. Yeager and associates[95] have reported successful identification of this anomaly

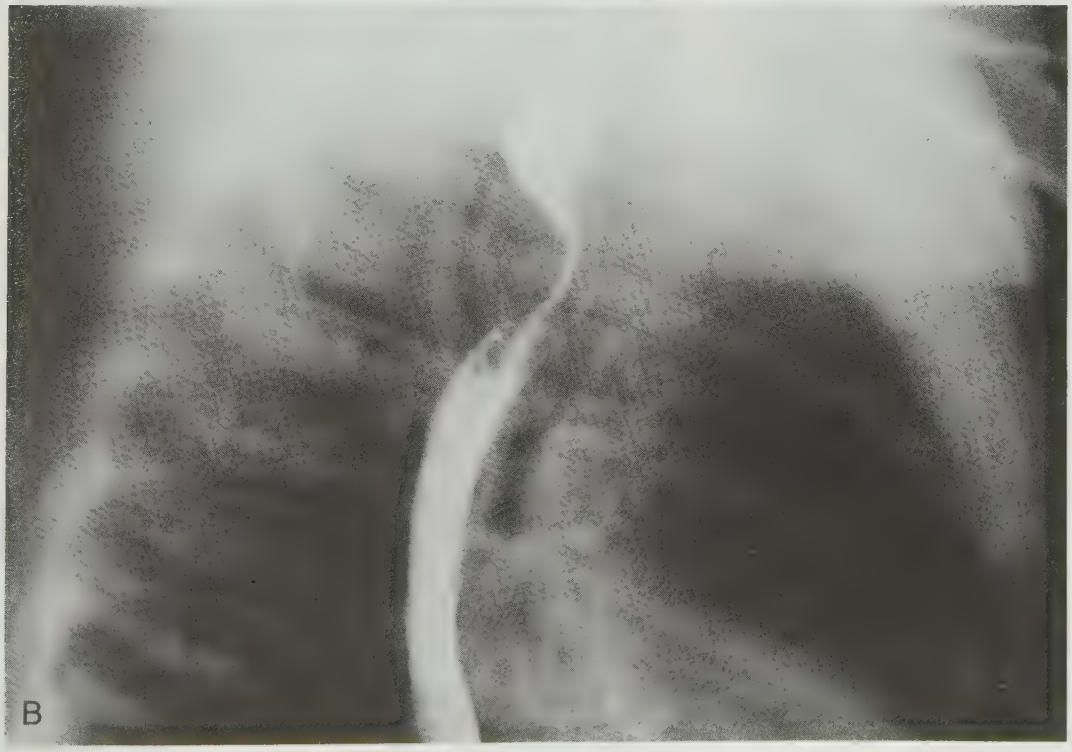

Fig. 82–15. Anteroposterior (A) and lateral (B) barium esophagograms in right aortic arch and anomalous left subclavian artery. The retroesophageal origin and course of the left subclavian artery are demonstrated by the oblique defect on the anteroposterior esophagogram (A). The presence of either a retroesophageal aorta or a retroesophageal diverticulum of the descending aorta is suggested by the large posterior defect on the lateral esophagogram (B).

Fig. 82–16. Suprasternal notch echocardiogram in the coronal plane in left aortic arch demonstrating normal branching of the right brachiocephalic artery (upper panel) to form the right carotid artery (RCA) and right subclavian artery (RSA). Anomalous origin of the right subclavian artery is suggested by the absence of branching (lower panel) of the first vessel to arise from the ascending aorta to the right (RCA). Ao = aorta. (From Huhta, J.C.: Pediatric Imaging/Doppler Ultrasound of the Chest: Extracardiac Diagnosis. Philadelphia, Lea & Febiger, 1986.)

Fig. 82–17. In right aortic arch with mirror-image branching, suprasternal notch echocardiography reveals the first branch of the aorta to the left (upper panel). This vessel, the left brachiocephalic artery, divides to form the left carotid artery (LCA) and the left subclavian artery (LSA). Counterclockwise rotation of the transducer from the coronal plane to the sagittal plane (lower panel) reveals the descending aorta (DAo) to the right of the trachea and spine and the remaining brachiocephalic vessels. Ao = aorta; IV = innominate vein; RCA = right carotid artery; RSA = right subclavian artery; AAo = ascending aorta. (From Huhta, J.C., Gutgesell, H.P., Latson, L.A., and Huffines, F.D.: Two-dimensional echocardiography of the aorta in infants and children with congenital heart disease. Circulation, *70*:417, 1984.)

Fig. 82–18. Suprasternal notch echocardiogram in a patient with right aortic arch and anomalous left subclavian artery. Scanning to the right in the sagittal plane (upper panel) reveals the ascending aorta (AAo) and descending aorta (DAo) coursing to the right. In the coronal plane (lower panel), absence of branching of the first branch of the aorta (Ao) to the left suggests anomalous origin of the left subclavian artery. A Kommerell's diverticulum (K) is seen in a retroesophageal location. RCA = right carotid artery; RSA = right subclavian artery; LCA = left carotid artery; IV = innominate vein. (From Huhta, J.C.: Pediatric Imaging/Doppler Ultrasound of the Chest: Extracardiac Diagnosis. Philadelphia, Lea & Febiger, 1986.)

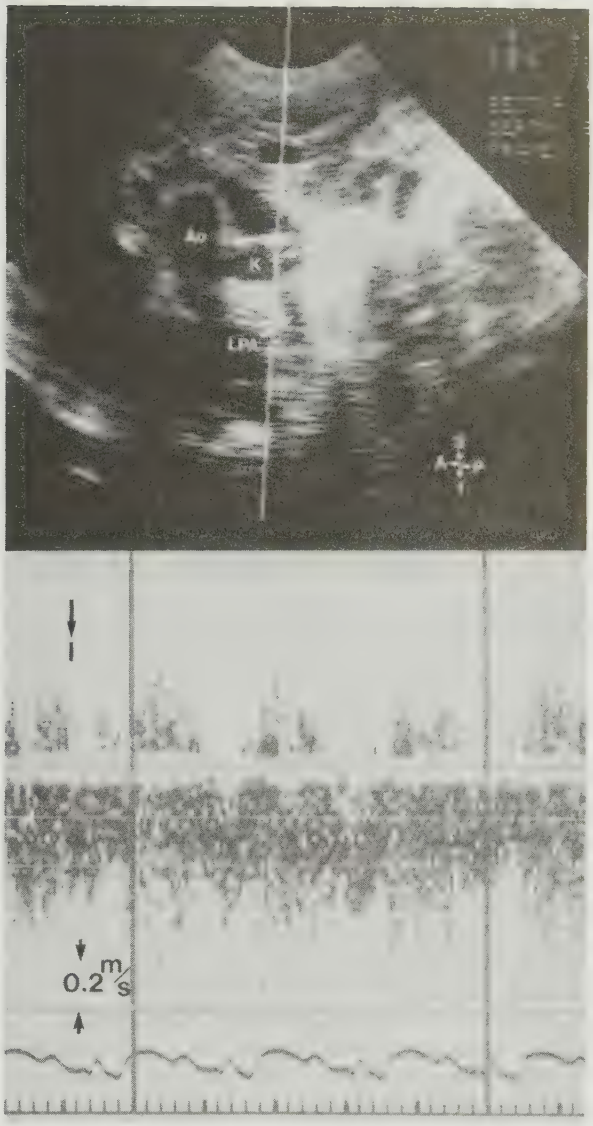

Fig. 82–19. The vascular ring is completed by demonstration of a patent ductus arteriosus on the left in the patient from Fig. 82–18. Pulsed Doppler sampling at the base of the left subclavian artery (upper panel) at its origin from the Kommerell's diverticulum (K) reveals continuous ductal flow away from the transducer toward the left pulmonary artery (LPA). Ao = aorta; m/s = meters per second. (From Huhta, J.C.: Pediatric Imaging/Doppler Ultrasound of the Chest: Extracardiac Diagnosis. Philadelphia, Lea & Febiger, 1986.)

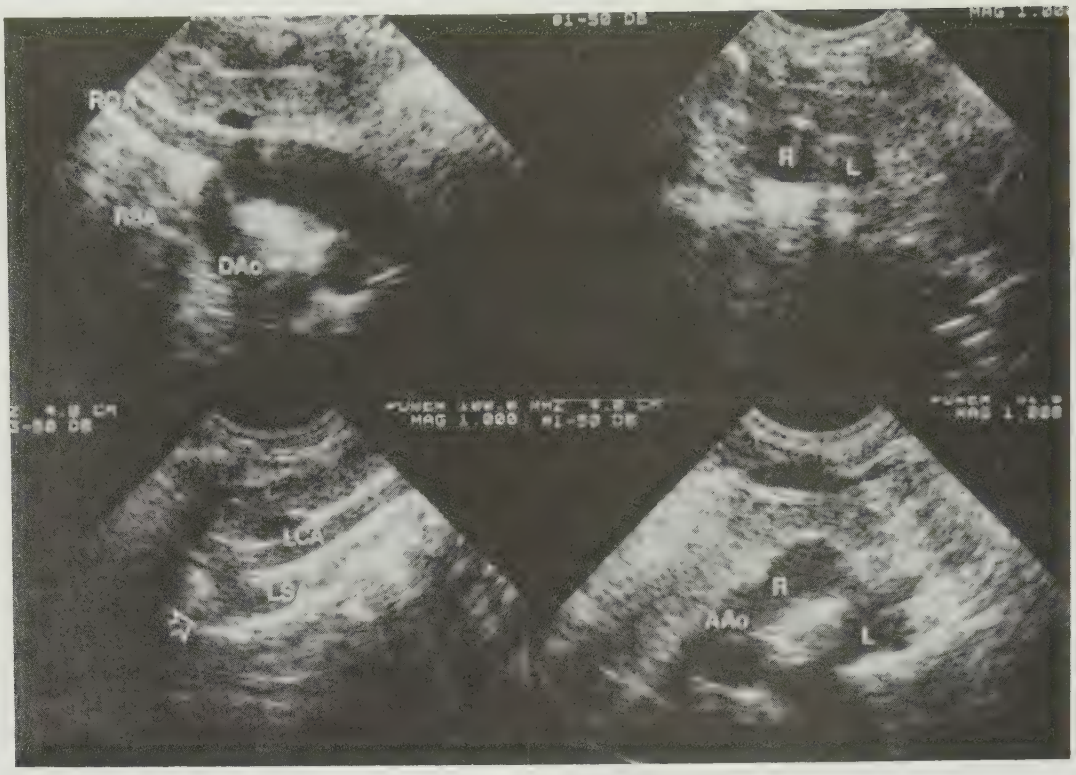

Fig. 82–20. Echocardiographic appearance of double aortic arch from the suprasternal notch. In the sagittal plane, the right aortic arch (upper left) and the left aortic arch (lower left) are demonstrated with separate origin of the carotid and subclavian arteries on each side. Scanning anterior in the coronal plane (upper right) reveals the characteristic bilateral echolucencies of double aortic arch. The right aortic arch (R) appears larger than the left aortic arch (L) in both the sagittal and coronal views. Scanning in the sagittal plane from right to left (lower right) reveals the complete vascular ring encircling the trachea and esophagus. RCA = right carotid artery; RSA = right subclavian artery; DAo = descending aorta; LCA = left carotid artery; LSA = left subclavian artery; AAo = ascending aorta.

in four of five infants known to have anomalous left pulmonary artery. Two echocardiographic features must be present to fulfill the diagnosis of anomalous left pulmonary artery. First, the normal origin of the left pulmonary artery from the main pulmonary artery in the short-axis plane must be absent. Scanning in the short-axis plane demonstrates the right pulmonary artery originating from the main pulmonary artery. However, the left surface of the main pulmonary artery is smooth without branching (Fig. 82–21). Second, origin of the left pulmonary artery from the right pulmonary artery must be established. In the suprasternal notch plane, an arterial branch can be seen to arise from the posterior surface of the right pulmonary artery. This vessel can be followed by scanning in the coronal plane and posterior to the usual plane of the right pulmonary artery. The vessel continues to the left and posterior to the trachea but anterior to the esophagus to enter the hilum of the left lung. The echocardiographic features of unilateral absence of a pulmonary artery and origin of one pulmonary artery from the ascending aorta have been described.[96,97]

Using the approach described above, Huhta and colleagues examined 22 patients with stridor and correctly identified a vascular ring in eight patients with no false-positive or false-negative diagnoses.[98] The vascular ring was the result of double aortic arch in five infants and right aortic arch with anomalous left subclavian artery and left ductus arteriosus or ligamentum arteriosus in three infants. The anatomy of the ring was confirmed at surgery in all cases. In four infants, surgery was performed on the basis of conventional noninvasive methods and echocardiography without angiography. Therefore it appears that when a vascular ring is suspected, the diagnosis can be made and sufficient anatomic detail can be provided by echocardiography to plan surgery. However, angiography is particularly useful in the unusual patient with a left arch and retroesophageal descending aorta and right ductus, since this form of vascular ring may be difficult to diagnose confidently using echocardiography alone. In addition, right aortic arch with a retroesophageal left subclavian and left ductus cannot be confidently distinguished from double aortic arch with atresia of the left arch between the left carotid and left subclavian by echocardiography or angiography. However, this distinction is not critical to surgical planning.

Angiography and Catheterization

The majority of aortic arch and pulmonary artery anomalies may be correctly identified by using a combination of standard chest radiography, barium esophagography, and two-dimensional echocardiography.[99] Certainly, when the suspected anomaly is minor, is unlikely to account for the patient's symptoms, or is minimally symptomatic, further invasive study is generally not indicated. However, greater anatomic detail than is provided by noninvasive methods may be necessary for surgical planning in patients who are significantly symptomatic. Angiography may be performed by using standard cineangiographic techniques or by using digital subtraction angiography.[15,18,90,11] The anatomy of the

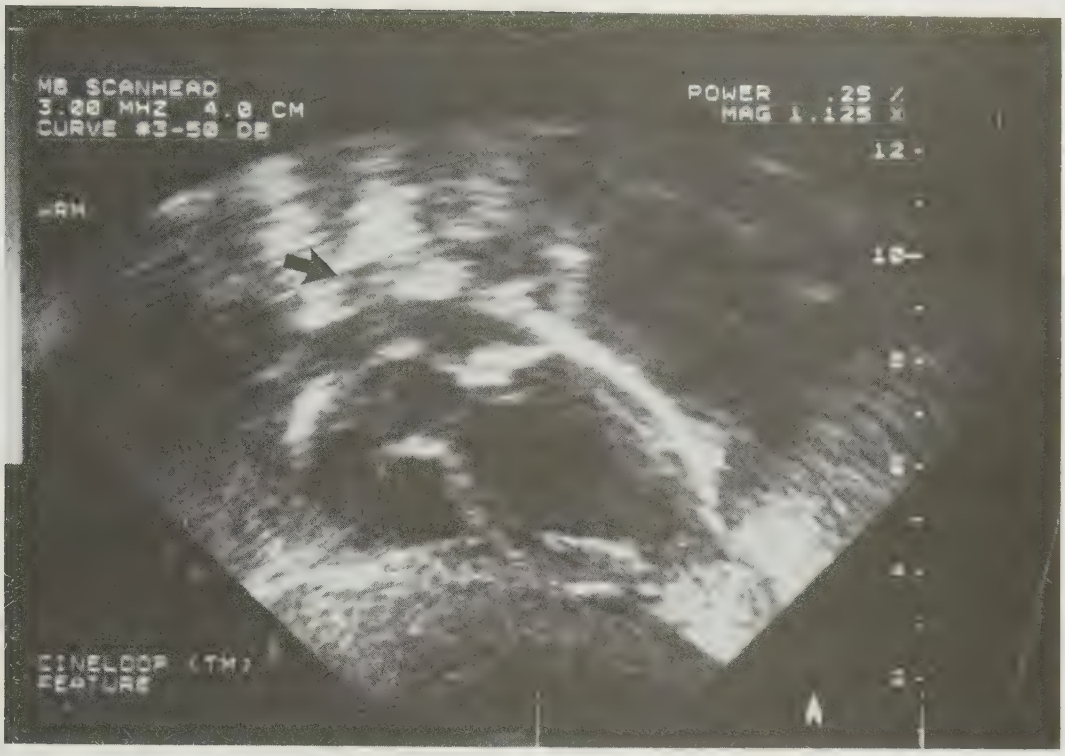

Fig. 82–21. Subxiphoid scan in a patient with anomalous origin of the left pulmonary artery from the right pulmonary artery. This scan demonstrates the absence of normal origin of the left pulmonary artery from the main pulmonary artery with posterior origin of the left pulmonary artery from the right (arrow). The course of the left pulmonary artery posterior to the trachea is also demonstrated from the subxiphoid scan.

aortic arch and descending aorta must be clearly demonstrated in addition to identifying the sequence of opacification of the brachiocephalic vessels. Standard anteroposterior and lateral projections may be used. However, in most cases, left or right oblique views with the addition of cranial angulation should be used to separate overlying structures and demonstrate the origin and course of the brachiocephalic vessels. Successful opacification of the aorta may be obtained with left ventriculography by venous catheterization with transseptal left heart catheterization, or by retrograde arterial catheterization. However, particularly when there is coexistent congenital heart disease, the best definition of aortic anatomy is obtained with aortic angiography. Digital subtraction angiography alone may provide excellent definition of aortic anatomy but does not allow cineangiographic demonstration of branching sequence. In addition, conventional catheterization provides an opportunity to study the presence and severity of associated heart disease. Use of a combination of these two methods, currently available in many cardiac catheterization laboratories, may prove to be the best approach to invasive imaging of aortic arch anomalies. The angiographic appearance of specific aortic arch and pulmonary artery anomalies is described in the following section.

CLINICAL SYNDROMES: COURSE, TREATMENT, AND PROGNOSIS

Among the many reported aortic arch and pulmonary artery malformations, a relative few account for the great majority of defects that are clinically recognized. The clinical features of these more common anomalies of the aortic arch and pulmonary artery are discussed below.

Left Aortic Arch, Aberrant Right Subclavian Artery

Left aortic arch with anomalous origin of the right subclavian artery is the most common aortic arch malformation noted on postmortem examination. The incidence of this abnormality in the general population is approximately 0.5%.[14] The left arch has a normal origin and course, but the right subclavian artery arises as the last branch of the arch and courses posterior to the esophagus. This occurs presumably as a result of abnormal regression of the embryonic right fourth aortic arch. The great majority of patients with anomalous right subclavian artery are asymptomatic, and the abnormality is discovered incidentally at esophagography for other conditions such as gastroesophageal reflux. In addition, anomalous right subclavian artery is frequently demonstrated on angiography in patients with congenital heart disease.[1] An anomalous right subclavian artery is often seen in patients with tetralogy of Fallot and left aortic arch[1] and would therefore have a significant bearing on the choice of systemic-to-pulmonary artery shunt employed for palliation of cyanosis. In addition, anomalous right subclavian artery may be present in patients with coarctation of the aorta[1,5,15] and often arises distal to the site of coarctation. In these patients, the blood pressure in the right arm and legs would not reflect the coarctation gradient. Likewise, when the anomalous right subclavian artery arises distal to the coarctation, rib notching will be observed only on the left, whereas when the anomalous right subclavian artery arises proximal to the coarctation, bilateral rib notching is observed.[1]

Clearly, most patients with anomalous right subclavian artery are asymptomatic,[12] although some older children and adults may occasionally experience dysphagia.[10,11] In these uncommon patients, surgical division and reimplantation of the anomalous subclavian artery may produce relief of dysphagia. However, prior to performing surgery, a thorough search should be made for other abnormalities that might account for the patient's symptoms.

Routine chest radiography does not demonstrate this anomaly, but barium esophagography is diagnostic. The oblique course of this vessel posterior to the esophagus in the anteroposterior projection and posterior indentation of the esophagus in the lateral or left anterior oblique projection are characteristic[5,13,15,46,89] (Fig. 82–13). Anomalous right subclavian artery may be recognized with two-dimensional echocardiography when, scanning from the suprasternal notch, the first branch of the aorta is to the right but the normal bifurcation into a right carotid artery and right subclavian artery cannot be demonstrated[87] (Fig. 82–16). Aortic angiography is indicated only in the unusual case requiring surgery. However, the presence or absence of an anomalous right subclavian artery should be noted when aortography is performed in patients with cyanotic congenital heart disease or with coarctation of the aorta (Fig. 82–22).

If symptoms of a vascular ring, such as stridor, wheezing, or cough, are present in a patient with an anomalous right subclavian artery, then consideration should be given to an alternative diagnosis such as laryngotracheomalacia. In rare instances, an anomalous right subclavian artery in association with a left aortic arch, retroesophageal descending aorta, and right ductus arteriosus or ligamentum produces a symptomatic vascular ring.[24,26,27] The retroesophageal descending aorta in these patients produces a large, rounded posterior indentation on a barium esophogram that is usually easily distinguished from the more shallow indentation produced by an anomalous right subclavian artery without a retroesophageal descending aorta. Angiography and surgery should be performed if significant symptoms are present.

The modern surgical approach to symptomatic anomalous right subclavian artery has been described[10,11] and should include division of the anomalous right subclavian artery, dissection of any other retroesophageal component that may be present, and reanastomosis of the anomalous vessel primarily or with prosthetic material. Establishing flow in the right subclavian artery is important to prevent ischemia to the right arm and also to prevent symptoms of cerebral ischemia secondary to the subclavian steal syndrome.[100–102] The surgical approach to patients with vascular ring due to a left aortic arch, retroesophageal descending aorta, anomalous right subclavian artery, and right ductus arteriosus or ligamentum requires a right thoracotomy to facilitate division of the ductus arteriosus or ligamentum and dissection of the retroesophageal component of the descending aorta.[24]

Double Aortic Arch

Double aortic arch is the most common clinically recognized form of vascular ring.[5,15,61,103–107] The ascending aorta divides anterior to the trachea into left and right arches passing to either side of the trachea. Usually, the right arch is larger than the left and passes posterior to the esophagus to join the descending aorta to the left of the midline.[1,22,23] Uncommonly, the left arch may be atretic betweeen the left subclavian artery and the descending aorta, between the left subclavian and the ductus arteriosus, or between the left subclavian and the left carotid artery. Rarely, there may be segmental atresia of the right arch.[24] However, the left arch may be larger and may course posterior to the esophagus and join the descending aorta on the right. A complete vascular ring is formed by the arches on each side of the trachea and esophagus with the ascending aorta anterior and the retroesophageal arch or descending aorta posterior. The ductus arteriosus is usually left sided and is not an essential component of the vascular ring. However, the length of the ductus or ligamentum may significantly affect the severity of symptoms encountered in individual patients. Double aortic arch presumably results from failure of regression of the eighth dorsal aortic arch segment on the right.[5]

Associated congenital heart disease is uncommon.[1,5,23] When

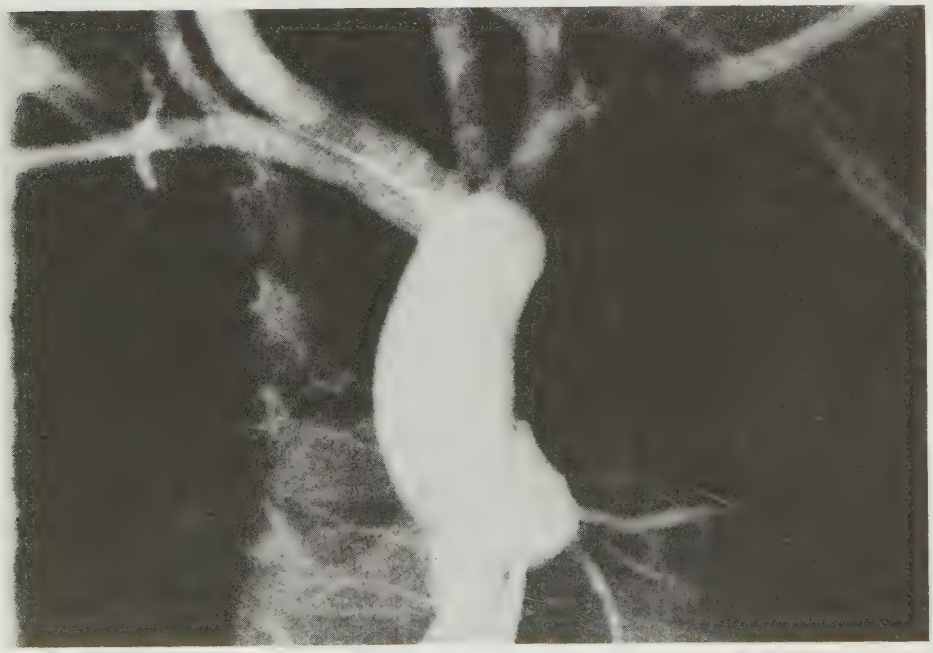

Fig. 82–22. Aortogram of a patient with anomalous origin of the right subclavian artery and tetralogy of Fallot. The right carotid artery arises as the first branch of the aorta but does not divide in the usual fashion. The right subclavian artery arises from the descending aorta as the last brachiocephalic branch.

present, the associated cardiac defects are usually cyanotic and include tetralogy of Fallot[1,23] and transposition of the great arteries.[48] In addition, coarctation may occur in an otherwise patent segment of either arch.[1,5,15]

Patients with double aortic arch are severely symptomatic in infancy with stridor, dyspnea, cough, and recurrent respiratory infections. Infants feed poorly because of severe respiratory distress and may prefer to lie with the head in an extended position. Life-threatening episodes of "reflex apnea" with cyanosis may occur.[62,105] The diagnosis of double aortic arch is often suggested on routine chest radiography.[5,15,46,89] Both arches may be seen to either side of the trachea in the anteroposterior projection, but a right aortic arch with left descending aorta is more commonly seen. This is because most patients with double aortic arch have a dominant right arch with a left descending aorta. There may also be evidence of hyperinflation of either or both lungs caused by obstruction of the lower trachea or tracheal narrowing because of tracheal and esophageal constriction (Fig. 82–12).

Barium esophagography will demonstrate bilateral indentations of the esophagus in the anteroposterior projection.[5,15,46,89] A large oblique defect may be produced by the retroesophageal arch (Fig. 82–14). In the lateral or left anterior oblique projection, a deep posterior indentation is seen and represents the retroesophageal component of the arch. There may also be an anterior more inferior indentation of the arch produced by posterior deviation of the trachea.[89] Characteristic findings of bilateral echolucencies of the double arch will be demonstrated by suprasternal notch echocardiography in the coronal plane[90,91,93] (Fig. 82–20). In addition, it is usually possible to determine the side of the dominant aortic arch and the side of the descending aorta. However, it is not possible to distinguish between right aortic arch with anomalous left subclavian artery and double aortic arch with atresia between the left carotid artery and the left subclavian artery using echocardiography alone.

In double aortic arch, angiography of the ascending aorta will demonstrate both arches, establish the dominant aortic arch, and often differentiate between right aortic arch with anomalous left subclavian artery and double aortic arch with segmental atresia of the left arch[15,21] (Fig. 82–23). As was noted above, angiography with left and right anterior oblique angulation is superior to anteroposterior and lateral projections for demonstration of each arch and the pattern of arterial branching. With patency of both arches, the ascending aorta bifurcates anterior and cephalad to the carina, and each arch courses posteriorly. Usually, the right arch is the larger of the two and can be seen to take a retroesophageal course and join with the left arch to the left of midline to form the descending aorta. The right and left common carotid arteries and subclavian arteries arise separately from each arch. When segmental atresia of the left arch is present, the branching pattern depends on the site of atresia. When atresia occurs between the left subclavian and the left carotid, the branching pattern of the left arch is similar to the branching pattern observed in right aortic arch with anomalous left subclavian artery. The left arch appears to terminate in the left carotid artery, and the left subclavian artery arises from the descending aorta. Usually, traction of the left carotid artery produces a deformity that offers a clue to the presence of the atretic segment and thus aids in the differentiation of this anomaly from right aortic arch with anomalous left subclavian. However, there may be no indication of an atretic segment, making the distinction between these two aortic arch anomalies difficult prior to surgery. Atresia may occur between the left subclavian artery and the ligamentum arteriosus or the ductus arteriosus, in which case the left arch terminates in what appears to be a left innominate artery with a large retroesophageal diverticulum to the left. Again, traction on the base of the left subclavian artery or constriction of the base of the left subclavian artery may suggest the presence of a double aortic arch with segmental atresia of the left arch.

Although some authors advocate a left thoracotomy in all cases, the surgical approach should be determined by the side of the dominant arch.[78,103–111] Since the right arch is dominant in most cases, a left thoracotomy, for division of the smaller or atretic left arch, is employed in most patients. When both arches are of equal size, the approach may be through a left or right thoracotomy, although Kirklin and associates advocate the latter.[78] The essential elements of surgery for double aortic arch include (1) division of the minor arch distal to the origin of the carotid or subclavian artery, (2) ligation and division of the ductus arteriosus or ligamentum arteriosus, and (3) complete dissection and mobilization of remaining components of the divided arch with dissection and division of any adventitial bands that form a part of the constricting mechanism.[6,78,103–108] Mortality is low, and eventual long-term relief of symptoms is usually achieved. However, short-term residual tracheal obstruction is the rule,[78] and most infants require intubation and aggressive attention to pulmonary toilet in the early postoperative period. Tracheomalacia may also coexist, leading to a need for long-term intubation or trachostomy.

Right Aortic Arch, Anomalous Left Subclavian Artery, and Left Ductus Arteriosus

Right aortic arch with anomalous left subclavian artery and left ductus arteriosus is the most common type of aortic arch anomaly that produces an anatomic vascular ring.[15] However, this group of abnormalities is usually asymptomatic[15,50] and therefore ranks as the second most common cause of symptomatic vascular ring requiring surgery.[103–107] The essential pathologic features include course of the arch to the right of the trachea with the first branch being the left carotid artery. The left subclavian artery arises from the descending aorta, and the ductus arteriosus originates from a retroesophageal diverticulum of the descending aorta and courses to the left to connect to the pulmonary artery. The descending aorta may take a retroesophageal course high in the thorax and descend on the left. In contrast to double aortic arch, the presence of a left ductus arteriosus is an essential component of the vascular ring. When the left ductus or ligamentum is absent, no vascular ring is formed.

Associated congenital heart disease is uncommon, occurring in less than 5% of patients with this group of abnormalities.[15,50] This is in contrast to right aortic arch with mirror-image branching in which cyanotic congenital heart disease is almost always present.[1,49–52]

As was noted above, patients with right aortic arch, anomalous left subclavian artery, and left ductus arteriosus are usually asymptomatic. When symptoms of tracheal or esophageal obstruction occur, they are similar to those encountered in patients with double aortic arch but are milder and often lead to presentation later in life.[106] Nonetheless, when symptomatic, patients will present with stridor, cough, and recurrent respiratory infections. Older patients

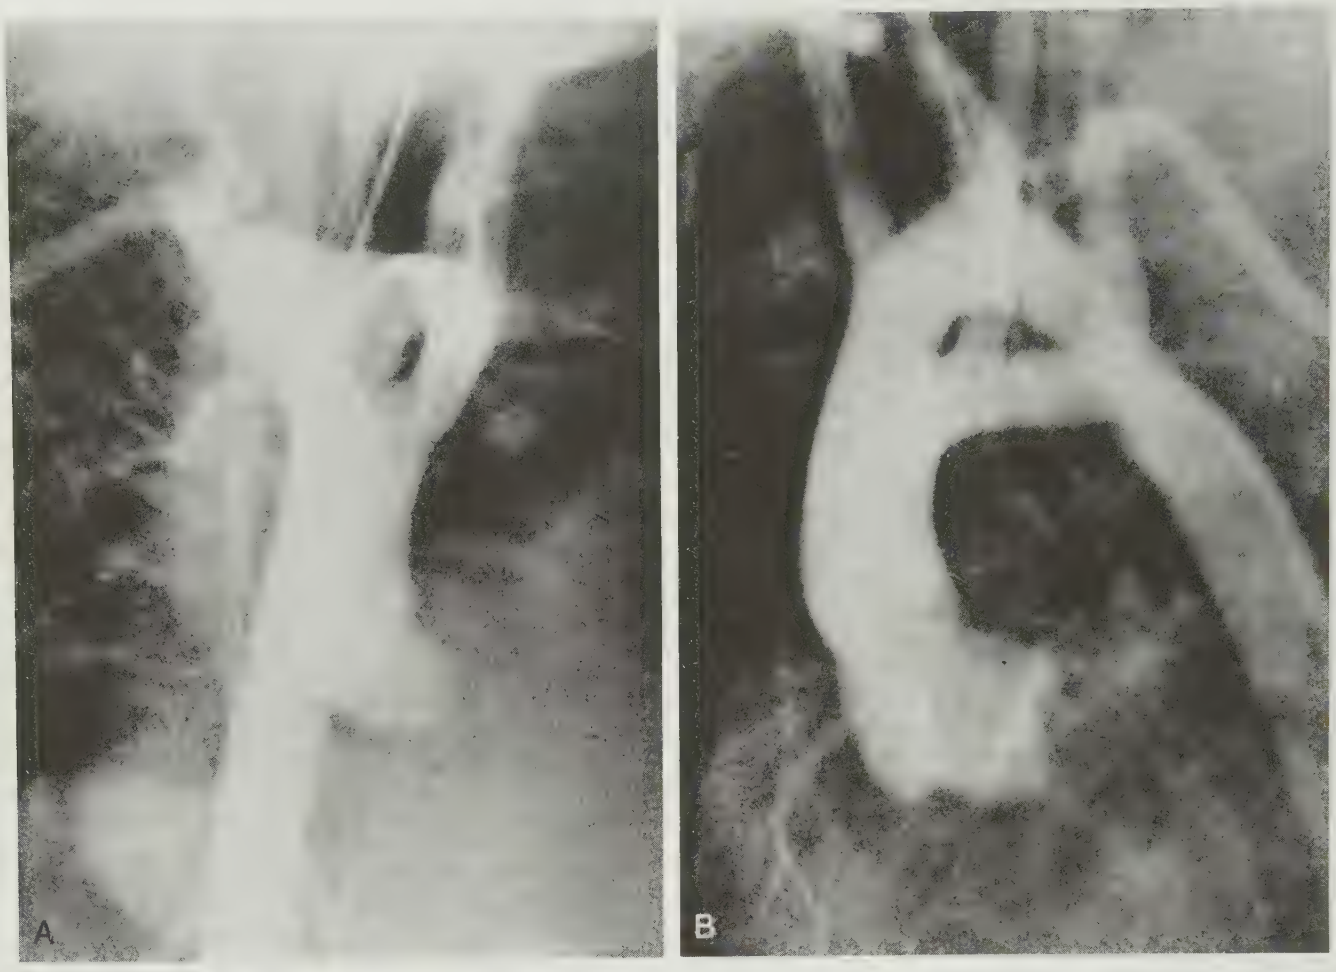

Fig. 82–23. Cranial (A) and left anterior oblique (B) cineangiograms in a patient with double aortic arch. The position of the trachea is demonstrated by the presence of the endotracheal tube. The ascending aorta divides to form the right aortic arch and left aortic arch. Both arches are patent, and separate origin of the carotid and subclavian arteries from each arch is demonstrated. In both views, the right aortic arch appears to be the larger of the two.

may complain of dysphagia and may not have a history of stridor or wheezing. Anteroposterior chest radiographs demonstrate deviation of the trachea to the left produced by the density of the right aortic arch (Fig. 82–11). The descending aorta may be on the left or the right. Barium esophagography demonstrates an oblique indentation from right to left (Fig. 82–15) in the anteroposterior projection and a posterior indentation of the esophagus in lateral and left anterior oblique views.[15,46,89] The size of the posterior indentation depends on the size of the retroesophageal component of the arch. A small indentation is produced by an anomalous left subclavian, whereas a larger indentation will be produced by a retroesophageal diverticulum or a retroesophageal descending aorta. On suprasternal notch echocardiography, the presence of a right aortic arch with anomalous left subclavian artery is confirmed by demonstrating the left carotid artery as the first branch of the arch[90] (Fig. 82–18). In sagittal views, the descending aorta is seen to course to the right of the trachea and descend on the right. A retroesophageal diverticulum can be demonstrated by scanning from right to left in a sagittal plane. When patent, the ductus arteriosus can be seen arising from the retroesophageal diverticulum and connecting to the pulmonary artery. Patency of the ductus arteriosus is confirmed by pulsed Doppler sampling in the pulmonary artery (Fig. 82–19). Thus echocardiographic demonstration of a right aortic arch with the first branch of the ascending aorta to the left without bifurcation strongly suggests the possibility of a vascular ring.

Angiography is reserved for patients in whom surgery is being contemplated. The first branch of the arch to opacify will be the left carotid artery, followed by the right carotid and subclavian arteries (Fig. 82–24). The arch courses to the right of the trachea as branching occurs; it then usually pursues a retroesophageal course, and the left subclavian artery arises from a diverticulum of the descending aorta. The ductus arteriosus opacifies when patent.

Stenosis of the anomalous left subclavian artery may be seen as it arises from the retroesophageal diverticulum and is probably produced by constriction of the ductus arteriosus at its origin at the bases of the left subclavian artery.[15,21] The origin of the left subclavian artery may be atretic, and therefore the left subclavian artery may be "isolated" from continuity with the aorta.[5,15] An isolated left subclavian then opacifies through the left vertebral artery by way of collaterals. The ductus arteriosus connects to a retroesophageal diverticulum when the left subclavian artery is anomalous. However, isolation of the left subclavian artery is more

Fig. 82–24. Retrograde aortic cineangiogram in the anteroposterior projection in a patient with right aortic arch and anomalous left subclavian artery. The left carotid artery arises as the first branch of the aorta, and the arch courses to the right of the trachea. The left subclavian artery originates from a retroesophageal Kommerell's diverticulum. The constriction at the base of the left subclavian artery (arrow) is probably produced by ductal constriction and indicates the presence of a left ductus arteriosus and a vascular ring.

often associated with right aortic arch with mirror-image branching where the isolated subclavian artery presumably results from atresia of the arch between the left carotid and subclavian arteries. In these patients, the ductus arteriosus connects to the base of the left subclavian artery as it does in most patients with right aortic arch and mirror-image branching.[5,15] This defect is commonly associated with tetralogy of Fallot[5,12,15,101] or other congenital cardiac defects. The essential difference between patients with isolation of the left subclavian artery and right aortic arch with mirror-image branching and those without mirror-image branching is the presence of a retroesophageal diverticulum in the latter group.

Surgery is indicated in patients who are symptomatic from significant tracheal or esophageal compression. The surgical approach includes ligation and division of the left ductus arteriosus or ligamentum, division of the left subclavian and reimplantation, and dissection of all retroesophageal components with division of all constricting bands.[78,103–107,109] As in the case of double aortic arch, surgical mortality is low, and long-term relief of symptoms is the rule.

Cervical Aortic Arch

Cervical aortic arch is an uncommon anomaly that may be described by three essential features.[28] First, there is cervical position of the aorta. The apex of the arch is above the clavicle and usually at the level of the fifth through the seventh cervical vertebrae.[1] Second, there is separate origin of the carotid artery contralateral to the arch. In addition, there is usually separate origin of the internal carotid, external carotid, and subclavian arteries on the side of the arch. Third, the descending aorta enters the thorax from the neck on the side of the arch, then crosses posterior to the esophagus in the upper thorax to descend and exit the thorax. There may be a ductus arteriosus or ligamentum originating from the descending aorta on the side contralateral to the arch. This in turn produces a vascular ring. Associated congenital heart disease is uncommon.[1,28,68] Cervical aortic arch may result from persistence of the embryonic right or left third dorsal aortic arch or from failure of the arch to descend into the thorax during development and growth of the embryo.[1,15,28,29]

Although many patients with cervical aortic arch are asymptomatic, when symptoms are present they may range from dysphagia to significant respiratory distress. The latter occurs when there is a coexisting vascular ring. There is always a pulsatile mass noted in the neck.[28] Compression of the mass produces a palpable reduction in leg pulses as well as the arm pulse on the side opposite the aortic arch. This physical finding is pathognomonic for cervical aortic arch. In addition, a thrill and murmur are present over the mass, and there may be other findings compatible with congenital heart disease on examination.

Routine chest radiography will demonstrate loss of the normal aortic knob on the left, widening of the superior mediastinum,[15] and an aortic density in the apex of the hemithorax on the side of the arch. There is a large posterior indentation of the esophagus in the lateral projection on esophagography.[15] Although cervical arch has been recognized by using two-dimensional echocardiography, the variations in arterial branching pattern that may be present make angiography a prerequisite to surgical repair. In a typical case, aortography reveals an elongated ascending aorta and the apex of the aortic arch above the clavicle (Fig. 82–25). Most often, the aortic arch is on the right. The aorta then turns caudally and reenters the thorax. The branching pattern of the brachiocephalic vessels is variable. The first branch is usually the left common carotid followed by the right internal carotid, the right external carotid, and the right subclavian artery. The left subclavian artery arises from the descending aorta after the descending aorta crosses the midline to the left. Rarely, with cervical position of the aortic arch, the arch and the descending aorta may be on the left, in which case a normal arterial branching pattern is observed. When the aortic arch and the descending aorta are on the right, the first branch of the aorta is a left common carotid artery with an anomalous left subclavian artery arising from the descending aorta.

Surgery is reserved for patients with symptoms of tracheal or esophageal compression or for patients with aneurysm formation or coarctation. The surgical approach to patients with cervical aortic arch has been described by Cooley.[111]

Fig. 82–25. Anteroposterior cineangiogram in an unusual patient with cervical aortic arch. The aortic arch ascends to the right with the apex above the right clavicle, then descends into the thorax to pursue a retroesophageal course to the left. The order of branching of the brachiocephalic vessels is left brachiocephalic artery, right internal carotid artery, right external carotid artery, and right subclavian artery. Typically, in contrast to this example, the subclavian artery on the side opposite the arch usually arises as the last branch of the aorta.

Anomalous Innominate Artery

Patients with stridor and respiratory distress in infancy associated with anterior compression of the trachea have been described with symptoms attributed to compression of the trachea by an anomalous origin and course of the innominate artery.[57–62] A number of investigators have advocated surgical intervention in patients with stridor and "reflex apnea" who manifest anterior tracheal compression on lateral chest radiographs and at bronchoscopy. Others have disputed the role of the innominate artery in producing symptoms and have cited the high incidence of tracheomalacia in affected infants and the frequent finding of anterior tracheal indentation in asymptomatic children.[63–67] It is clear that the innominate artery may arise more distal on the aortic arch and produce a striking degree of tracheal indentation in its course across the anterior mediastinum. However, Swischuk[63] and Berdon and associates[89] have emphasized the role of anterior mediastinal crowding, which is demonstrable on lateral chest radiographs in normal infants, in producing apparent anterior tracheal compression. In addition, varying degrees of anterior tracheal compression by the innominate artery may be seen at bronchoscopy in asymptomatic children.[67] This finding is seen in both asymptomatic and symptomatic infants and apparently resolves with age.

Symptoms ascribed to innominate artery compression are basically the same as those caused by tracheomalacia. Affected infants have cough, stridor, and dyspnea and may have episodes of apnea and cyanosis. Infants who experience apnea and cyanosis have a serious prognosis. In addition to the findings on chest radiographs and bronchoscopy noted above, echocardiography will demonstrate a normal left aortic arch with the first branch being the innominate artery to the right. Barium esophagography is normal, excluding vascular rings and vascular slings. In infants experiencing apnea, the diagnosis of more common causes of apnea should be vigorously pursued.

Most affected infants improve without surgical intervention. It is interesting that the contemporary surgical approach for symptomatic tracheomalacia is essentially the same as the procedure advocated for symptomatic anomalous innominate artery.[64] The indication for surgery in both conditions is the severity of symptoms. The innominate artery, the aorta, and the anterior mediastinal fascia are sutured to the posterior sternal periosteum in an attempt to relieve compression. Some authors have reported good relief of symptoms and have concluded that the innominate artery must have been the cause of stridor and respiratory distress.[57–62] However, similar results are obtained in severely symptomatic patients with tracheomalacia who do not have distal origin of the innominate artery or striking discrete tracheal compression. It is likely that the primary diagnosis in the majority of patients is localized or diffuse tracheomalacia and that the effect of surgery is to reduce the extrinsic compression produced by "anterior mediastinal crowding."[63]

Anomalous Left Pulmonary Artery

Anomalous origin of the left pulmonary artery is a rare congenital anomaly that produces severe tracheobronchial obstruction in most affected patients. A normal left pulmonary artery is absent, and the left lung is supplied wholly or partially by an anomalous left pulmonary artery arising from the distal right pulmonary artery. Tracheal and bronchial compression is produced as this artery courses posterior and caudal to the right main stem bronchus and to the left, posterior to the trachea and anterior to the esophagus. The vessel then proceeds to the left hilum posterior to the left bronchus and enters the lung. The course of the vessel to the right of the trachea produces deviation of the lower trachea to the left. The resulting compression of the right main stem bronchus and lower trachea leads to airway obstruction primarily affecting the right lung. However, compression of the lower trachea and left main stem bronchus may occur, resulting in bilateral obstruction.

The anomalous left pulmonary artery is usually the sole arterial supply to the left lung. However, arterial supply to the left lower lobe by the anomalous left pulmonary artery with arterial supply to the left upper lobe by a left pulmonary artery in the normal position has been described.[34] In addition, partial arterial supply to the right upper lobe by an arterial branch originating from the anomalous left pulmonary artery has also been described.[71] The frequent occurrence of associated congenital defects, particularly those affecting the lung, is described above.

Symptoms of anomalous left pulmonary artery occur early in the great majority of patients. Although two thirds of affected infants are symptomatic by one month of age,[36] the diagnosis is made in only 14% of these patients. In some cases, the anomaly is not recognized until postmortem examination. Symptoms include severe respiratory distress with stridor, wheezing, cyanosis, and recurrent pneumonitis. Obstructive apnea may occur and can be fatal. Unlike aortic vascular rings, dysphagia is rare, since the anomalous left pulmonary artery passes anterior to the esophagus without significant esophageal compression. Although the majority of patients are severely symptomatic, asymptomatic and mildly affected patients have been observed.[77,112] Nonetheless, in severely affected infants, death may occur within the first six months of life unless surgery is performed.[70]

On anteroposterior chest radiographs, the lower trachea is deviated to the left and may appear "squeezed together."[1] Hyperinflation of the right lung is commonly observed because of compression of the right main stem bronchus. The degree of hyperinflation may be severe and may lead to a mistaken diagnosis of congenital lobar emphysema. Left-sided hyperinflation may also be seen on chest radiographs because of obstruction of the carina or left bronchus. Atelectasis of a single lobe or lung is observed in patients with severe obstruction. A mediastinal mass may be seen posterior to the trachea and anterior to the esophagus at the level of the carina.[36]

Barium esophagography usually demonstrates a characteristic anterior indentation of the esophagus on the lateral projection[15,76,89] (Fig. 82–26). The esophagus may be displaced to the right in the frontal projection and demonstrates an oblique impression immediately posterior to the carina. Demonstration of characteristic echocardiographic findings in affected patients may obviate the need for esophagography. Scanning in a coronal plane from the suprasternal notch (Fig. 82–21) and from the parasternal short axis demonstrates absence of the normal bifurcation of the main pulmonary artery into right and left pulmonary arteries. The left pulmonary artery appears to be absent. Examination of the right pulmonary artery will reveal a vessel arising from the posterior surface of the right pulmonary artery that can be followed posterior to the trachea and anterior to the esophagus. The vessel then passes anterior to the descending aorta and enters the left hilum. Yeager and associates[95] have described imaging of the anomalous left pulmonary artery from the subxiphoid position in five patients with anomalous left pulmonary artery with successful identification of the anomaly in four. The same principles of diagnosis apply to the subxiphoid view with demonstration of absence of a normal left pulmonary artery and origin of the anomalous left pulmonary artery from the posterior surface of the right pulmonary artery. However, the course of the left pulmonary artery with respect to the trachea and esophagus may be more difficult to image from the subxiphoid position. In addition to demonstration of the anomalous left pulmonary artery, two-dimensional echocardiography accurately diagnoses and describes associated cardiac defects.

Although the presence of a "vascular sling" can be established noninvasively, pulmonary artery angiography remains necessary to delineate the anatomic detail necessary for surgical correction. Mixed arterial supply to the right or left lung by the anomalous left pulmonary artery will necessitate alterations in surgical technique and cannot be completely described by using noninvasive

Fig. 82–26. Barium esophagogram in a patient with anomalous left pulmonary artery. In the anteroposterior projection (left panel), the trachea is deviated to the left, and there is compression of the esophagus on the left. In the lateral projection (right panel), the characteristic anterior indentation of the esophagus just above the carina can be seen. (From Gumbiner, C.H., Mullins, C.E., and McNamara, D.G.: Pulmonary artery sling. Am. J. Cardiol., *45*:311, 1980.)

techniques alone. A vascular sling produced by an anomalous ductus arteriosus[8,113] could be mistaken for an anomalous left pulmonary artery by esophagography. However, both of these unusual situations, with exception of partial supply to the right lung by the anomalous left pulmonary artery, should be suspected on two-dimensional echocardiography if the criteria described above for the diagnosis of anomalous left pulmonary artery are strictly observed.

On angiography, the origin and course of the anomalous left pulmonary artery are best demonstrated by contrast injection into the main pulmonary artery using a steep cranial angulation of 60 to 70% or by using the sitting-up view[21,77,112] (Fig. 82–27). In the anteroposterior projection, absence of a normal left pulmonary artery can be seen, but the origin of the anomalous left pulmonary is partially obscured by the right pulmonary artery. Catheterization is also indicated to assess the severity of associated cardiac defects.

Survival of symptomatic infants is unlikely without early surgical intervention. Therefore surgery should be performed early in infants suffering from severe respiratory obstruction. Planning the surgical approach for these patients is often complicated by the presence of associated congenital heart disease as well as pulmonary anomalies. Patients who are free of respiratory obstruction or are mildly affected do not require surgical correction of the anomalous left pulmonary artery. However, surgery for repair of associated cardiac defects may be necessary. Potts[114] described the first surgical procedure for correction of anomalous

Fig. 82–27. Anteroposterior (A) and cranial (B) cineangiograms in a patient with anomalous left pulmonary artery. In the anteroposterior right ventricular cineangiogram (A), the absence of a normal left pulmonary artery can be seen as well as the origin of the left pulmonary artery from the right pulmonary artery. However, both the origin of the left pulmonary artery and its course posterior to the trachea are seen to better advantage with main pulmonary artery cineangiography with steep cranial angulation (B). (Part B is from Gumbiner, C.H., Mullins, C.E., and McNamara, D.G.: Pulmonary artery sling. Am. J. Cardiol., *45*:311, 1980.)

left pulmonary artery in 1954. Although there have been many subsequent reports describing successful treatment of this anomaly by surgery,[36,76,78,103–105,115,116] mortality remains high. Sade and associates,[36] Koopot and associates,[76] and Kirklin and associates[78] have reviewed the surgical experience with anomalous left pulmonary artery. The major approach to this lesion involves division of the anomalous vessel and reanastomosis to the main pulmonary artery anterior to the trachea. This may be accomplished through either a left posterolateral thoracotomy or median sternotomy with cardiopulmonary bypass.[36,76,78] Surgical and postoperative mortality is approximately 40 to 50%. Coexisting tracheal or bronchial stenosis is disproportionately prevalent and severe in nonsurvivors and is undoubtedly a major contributing factor to postoperative death. This has led some authors to recommend bronchographic or bronchoscopic[77] evaluation of selected surgical candidates, since surgical reconstruction of obstructed bronchi may be required. In addition, careful attention to tracheobronchial toilet in the postoperative period is necessary to avoid airway obstruction caused by secretions. Despite a high incidence of postoperative stenosis of the left pulmonary artery, surgical survivors are often free of significant symptoms at long-term followup.[36,78] However, some degree of airway obstruction may persist in up to 45% of patients who survive surgery.[117]

Unilateral Absence of One Pulmonary Artery

Unilateral absence of one pulmonary artery is an uncommon congenital defect. Forty percent of cases occur without associated cardiac defects, whereas the remaining patients have tetralogy of Fallot, patent ductus arteriosus, or ventricular septal defect.[31] The absent pulmonary artery is usually opposite the side of the aortic arch. When associated with tetralogy of Fallot, the absent pulmonary artery is usually on the left. In addition, patients with atrial septal defects, aortopulmonary window, subaortic stenosis with coarctation, transposition, aberrant left subclavian artery, and truncus arteriosus have been reported.[31–33] The distal pulmonary artery on the affected side can often be identified at surgery; thus the term "occult pulmonary artery" as suggested by Presbitero and associates[32] may be more appropriate.

Patients without associated cardiac defects are often asymptomatic but may experience recurrent pneumonitis, bronchiectasis, or hemoptysis. When associated congenital heart disease is present, symptoms are generally those of the associated defect. Patients with left-to-right shunts may experience severe symptoms of pulmonary congestion, since both the normal cardiac output and the left-to-right shunt must perfuse the normally connected pulmonary artery. Likewise, there are no specific physical findings that indicate unilateral absence of a pulmonary artery. Most patients have a systolic murmur at the left sternal border. Those with coexisting cardiac defects have compatible physical findings.

Differential perfusion of the lungs with reduced vascular markings may not be apparent in infants in chest radiographs. However, in older children and adults, increased vascular markings on the side with normal pulmonary artery connection and decreased markings on the affected side may be seen.

Absence of a pulmonary artery will be readily apparent by two-dimensional echocardiography, particularly in short-axis and suprasternal notch scans in which the normal bifurcation of the main pulmonary artery is absent. However, a careful search should be made for connection of the involved pulmonary artery to the ascending aorta or, in the case of anomalous left pulmonary artery, to the right pulmonary artery.[84,90] Identification of ductal supply to the occult pulmonary artery should be possible in neonates using combined high-frequency (7.5 or 10 mHz) mechanical scanning and pulsed Doppler. In addition, associated cardiac defects will be identified by two-dimensional echocardiography as well as the side of the aortic arch. Perfusion lung scan, in the absence of right-to-left cardiac shunts, demonstrates perfusion of only the normally connected lung. Right ventricular or pulmonary artery angiography will demonstrate the absent pulmonary artery and the normally connected pulmonary artery (Fig. 82–28). Aortography is useful in identifying the source of systemic arterial supply to the affected lung. Cardiac catheterization also allows accurate assessment of pulmonary artery pressure and resistance in the normally connected lung. Approximately 20% of patients without associated left-to-right shunts will demonstrate evidence of pulmonary hypertension, whereas 88% of those with left-to-right shunts have pulmonary hypertension.[31] Although pulmonary hypertension is not present in patients with tetralogy of Fallot, catheterization following repair of this defect may demonstrate elevated pulmonary resistance.[31]

In patients with isolated unilateral absence of one pulmonary artery, treatment depends on the severity of symptoms. Pneumonitis may be treated medically, but if severe recurrent lung infections or hemoptysis occurs, consideration should be given to pneumonectomy of the affected lung. The presence of pulmonary vascular disease in the unaffected lung would preclude pneumonectomy. Early surgical identification of the occult pulmonary artery may allow establishment of arterial supply and maintenance of growth of the true pulmonary artery, thus discouraging collateralization.[32] However, in the absence of associated congenital heart disease, many of these infants will be asymptomatic and therefore escape recognition.

Patients with coexisting left-to-right shunts should undergo early surgical repair of the intracardiac or extracardiac shunt to prevent development of irreversible pulmonary hypertension.[31] Surgery should be performed in the first three to six months of life, although pulmonary hypertension may progress despite surgical intervention.

Origin of One Pulmonary Artery from the Ascending Aorta

As was noted above, origin of one pulmonary artery from the ascending aorta is a rare anomaly, occurring in 0.05% of patients with congenital heart disease.[80] In most patients, the right pulmonary artery arises from the ascending aorta and is usually the same size as, or larger than, the left pulmonary artery. The vessel connects to the aorta just above the aortic valve and on the right or posterior and courses directly to the right hilum. Most patients with origin of one pulmonary artery from the ascending aorta have a patent ductus arteriosus.[80–82] Cardiac defects associated with origin of the right pulmonary artery from the ascending aorta include ventricular septal defect, aortopulmonary window, coarctation of the aorta, interrupted aortic arch, atrial septal defect, and contralateral pulmonary vein stenosis.[78,80]

In some patients, the left pulmonary artery originates from the ascending aorta. This occurs as an isolated anomaly in approximately 40% of cases. In these patients, the aortic arch is usually on the right. In the remaining patients with origin of the left pulmonary artery from the ascending aorta, tetralogy of Fallot is

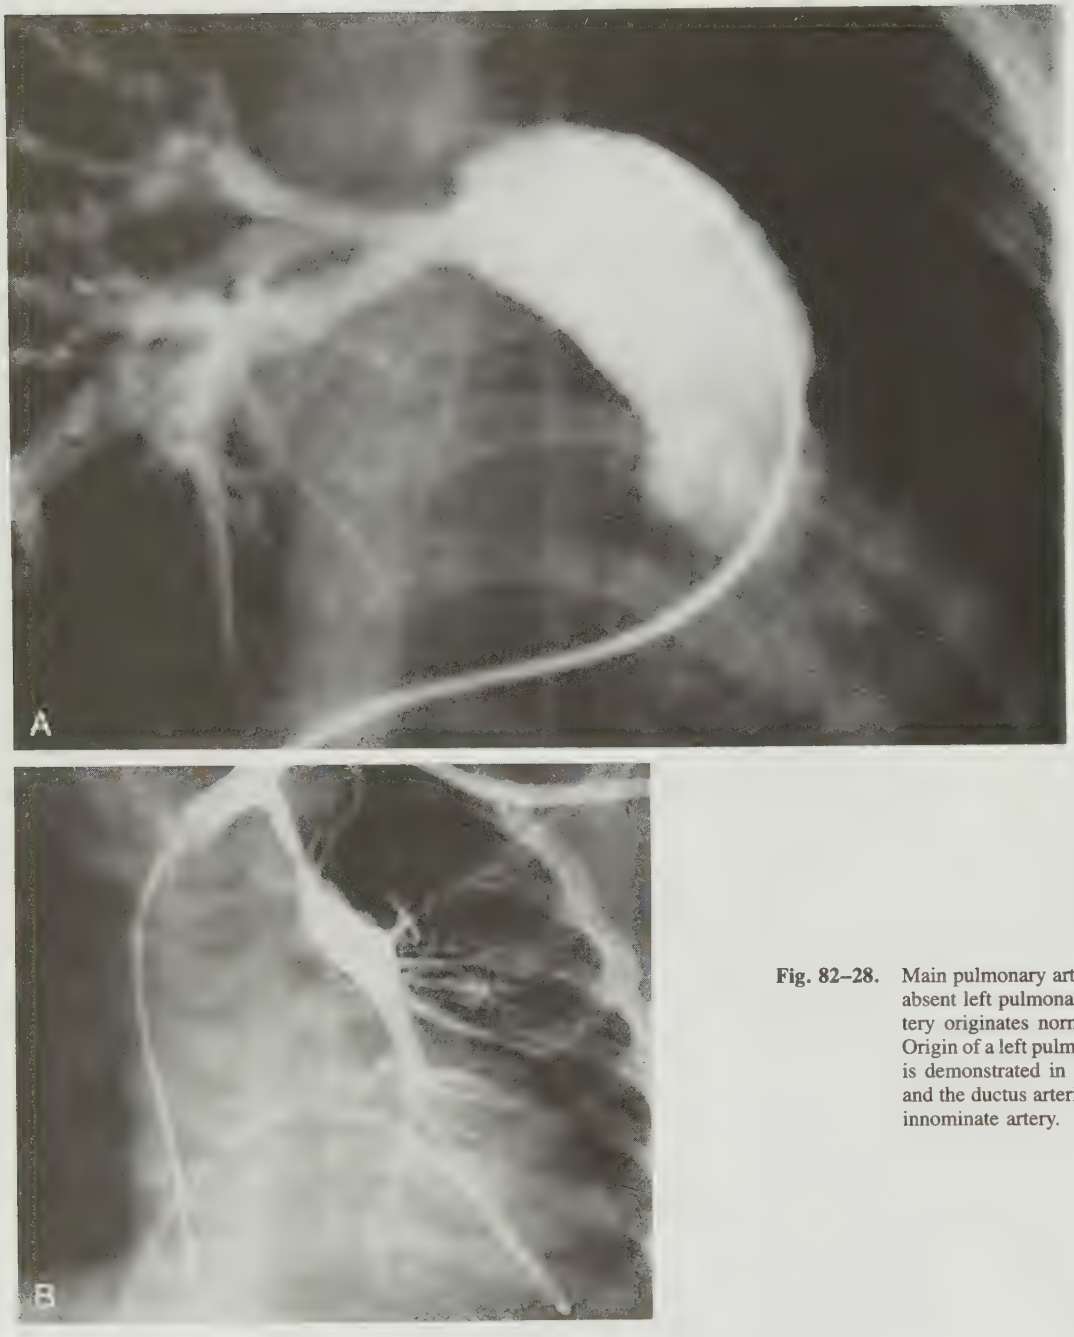

Fig. 82–28. Main pulmonary artery cineangiogram (A) in a patient with absent left pulmonary. The hypoplastic right pulmonary artery originates normally from the main pulmonary artery. Origin of a left pulmonary artery from a left ductus arteriosus is demonstrated in part B. The aortic arch is to the right, and the ductus arteriosus originates from the base of the left innominate artery.

often present.[81,84] In addition, tetralogy of Fallot may also occur in patients with anomalous origin of the right pulmonary artery.[78,80,84] The embryopathogenesis of anomalous origin of one pulmonary artery from the ascending aorta is discussed above.

Patients with origin of one pulmonary artery from the ascending aorta characteristically present in early infancy with severe congestive heart failure. Affected infants often manifest cyanosis in the absence of cyanotic congenital heart disease.[80] In these patients, cyanosis results from a right-to-left shunt at the ductal level caused by pulmonary hypertension.[33,80] The heart is often massively enlarged on chest radiographs, and the pulmonary vascular markings either are symmetrically increased or are greater on the affected side. The diagnosis may be made by two-dimensional echocardiography[84,90,95,97] (Fig. 82–29). The origin of the anomalous pulmonary artery from the aorta, usually on the right, can be demonstrated in the short-axis and suprasternal notch scans and may be distinguished from aortopulmonary window by demonstrating lack of continuity of the right and left pulmonary arteries.[97] The presence of a ductal shunt, which is usually bidirectional, can be established by pulsed Doppler interrogation of the ductus arteriosus and main pulmonary artery. Echocardiographic examination will demonstrate two arterial valves except in some patients with severe pulmonary atresia associated with extreme hypoplasia or absence of the main pulmonary artery.[84] In these patients, the differentiation from truncus arteriosus may be aided by demonstrating a blind right ventricular outflow tract and three aortic valve cusps. In addition, echocardiography will clearly delineate other associated cardiac defects. Catheterization is useful in determining the pulmonary artery resistance in the normally connected lung. Aortography will demonstrate the anomalous vessel, and ventricular cineangiography will identify associated cardiac defects (Fig. 82–30).

Although significant pulmonary vascular obstructive disease is not present in infants who die before six months of age, obstructive changes may be present soon thereafter.[80] Without surgical intervention, most patients will die by six months of age.[78] Pulmonary hypertension is present on the affected side in all patients except the rare patient with stenosis of the origin of the anomalous vessel.[34,80] Arterial pressure in the normally connected pulmonary artery is usually at systemic levels except in patients with tetralogy of Fallot. Thus early surgical repair is indicated when the diagnosis of unilateral origin of a pulmonary artery from the ascending aorta is established. Accurate assessment of pulmonary resistance in the normally connected lung is important in patients presenting after six months of age. Significant elevation in resistance may be a contraindication to surgery in these patients. Surgical division and anastomosis of the affected artery to the main pulmonary artery are performed through a median sternotomy using cardiopulmo-

Fig. 82–29. Echocardiographic demonstration of origin of the right pulmonary artery from the ascending aorta. In the upper and lower left panels, the right pulmonary artery (RPA) originates from the ascending aorta (Ao) without communication with the left pulmonary artery (LPA). In the upper and lower right panels, the origin of the left pulmonary artery from the main pulmonary artery (MPA) is established. The presence of an aortic valve (AV) and pulmonary valve (PVal) distinguishes this condition from truncus arteriosus. LA = left atrium. (From King, D.L., Huhta, J.C., Gutgesell, H.P., and Ott, D.A.: Two-dimensional echocardiographic diagnosis of anomalous origin of the right pulmonary artery from the aorta: Differentiation from aortopulmonary window. J. Am. Coll. Cardiol., *4*:351, 1984.)

Fig. 82–30. Aortic cineangiography in a patient with origin of the right pulmonary artery from the ascending aorta. The right pulmonary artery arises from the ascending aorta just above the aortic sinuses of Valsalva. The presence of two semilunar valves and normal origin of the left pulmonary artery distinguish this condition from truncus arteriosus. (From King, D.L., Huhta, J.C., Gutgesell, H.P., and Ott, D.A.: Two-dimensional echocardiographic diagnosis of anomalous origin of the right pulmonary artery from the aorta: Differentiation from aortopulmonary window. J. Am. Coll. Cardiol., *4*:351, 1984.)

nary bypass with hypothermia.[78] Surgical results in patients without associated cardiac defects or with patent ductus arteriosus are good,[78,80,82,118] although results in patients with associated cardiac defects other than patent ductus arteriosus are generally poor. Survivors of surgery in infancy usually have normal pulmonary artery pressure and resistance at followup.[80,82,118]

CHAPTER 83

Congenital Coronary Artery Anomalies

David J Driscoll

CORONARY ARTERY ANOMALIES

As Leonardo da Vinci said, "The heart in itself is not the beginning of life; but it is a vessel formed of thick muscle, vivified and nourished by the artery and vein as are the other muscles."

Normal Coronary Anatomy

The term "coronary" is derived from the Latin "coronarius," or "crown," because the coronary arteries cover the heart in a fashion reminiscent of a crown covering a head. Usually, there are two major coronary arteries, which originate from the right and left aortic sinuses of Valsalva. Commonly, however, branches of the right or left coronary artery have separate origins from the sinuses of Valsalva. The sinuses of Valsalva consist of portions of the aorta between the sinotubular ridge and the aortic valve leaflets. The third, or posterior, sinus of Valsalva is usually slightly larger than the left or right sinus of Valsalva, is unassociated with a coronary artery orifice, and is termed the noncoronary sinus of Valsalva or noncoronary aortic cusp.[1]

The Left Coronary Artery

The left main coronary artery arises from the left sinus of Valsalva and courses only a short distance (less than 4 cm in the adult) before dividing into the left circumflex and left anterior descending coronary arteries (Fig. 83–1). The left circumflex coronary artery varies considerably in size depending upon whether the posterior descending coronary artery is a branch of the right coronary artery ("right-dominant coronary system") or a branch of the circumflex coronary artery ("left-dominant coronary system"). If the posterior descending coronary artery originates from the circumflex coronary artery (this occurs in about 10% of patients), the circumflex coronary artery is large. In some patients with a dominant right coronary artery, the circumflex coronary artery may be quite small. The circumflex coronary artery travels under the left atrial appendage and along the groove of the left atrioventricular valve. In 50% of cases, the sinus node artery arises from the left circumflex coronary artery. The sinus node artery courses under the left atrial appendage, penetrates the interatrial septum, encircles the base of the superior vena cava, and supplies the sinus node. When the sinus node artery is not a branch of the left circumflex coronary artery, it is a branch of the right coronary artery. Kugel's artery may arise from the left circumflex coronary artery (alternatively, it may arise from the right or left main coronary artery) and courses through the interatrial septum anastomosing with the artery to the atrioventricular node. Marginal branches arise from the left circumflex coronary artery and supply areas of the lateral wall of the left ventricle. The largest marginal branch is termed the obtuse marginal. The left atrial circumflex artery may arise from the left circumflex coronary artery and supply the left posterior atrial wall. Occasionally, the sinus node artery can arise from the left atrial circumflex coronary artery.

The left anterior descending coronary artery appears to be a direct continuation of the left main coronary artery rather than a branch of it. The left anterior descending coronary artery travels along the interventricular sulcus and may continue around the apex of the heart onto the posterior interventricular sulcus to anastomose with the posterior descending coronary artery. The left conus artery is the first branch of the left anterior descending coronary artery and may anastomose with the conal branch of the right coronary artery, forming the "circle of Vieussens." Four to six septal

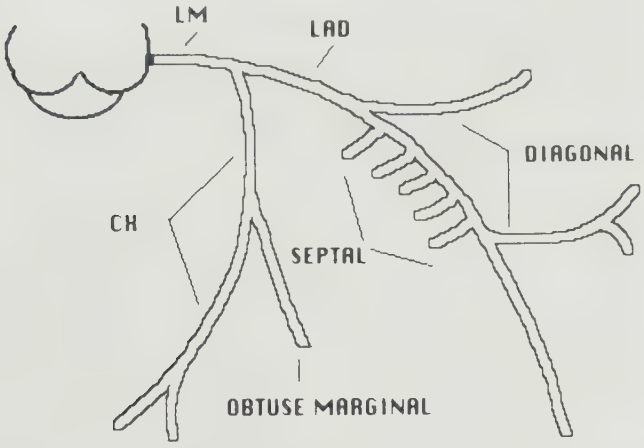

Fig. 83–1. Normal left coronary artery system. CX = circumflex; LM = left main; LAD = left anterior descending coronary arteries.

branches of the left anterior descending coronary artery penetrate the ventricular septum and anastomose with posterior septal branches arising from the posterior descending coronary artery. The left anterior descending coronary artery gives rise to diagonal branches that supply the anterior surface of the right and left ventricles and the right ventricular infundibulum.

The Right Coronary Artery

The right coronary artery arises from the right aortic sinus of Valsalva and courses behind the pulmonary artery beneath the right atrial appendage and along the right atrioventricular groove (Fig. 83–2). At the acute margin of the heart, it turns posteriorly and caudally over the diaphragmatic surface of the heart. The branches of the right coronary artery include the right conal branch, the sinus node artery, an atrial branch, right ventricular muscle branches (including the acute marginal branch), posterior descending coronary artery, atrioventricular node artery, and septal branches. The right conus artery is the first branch of the right

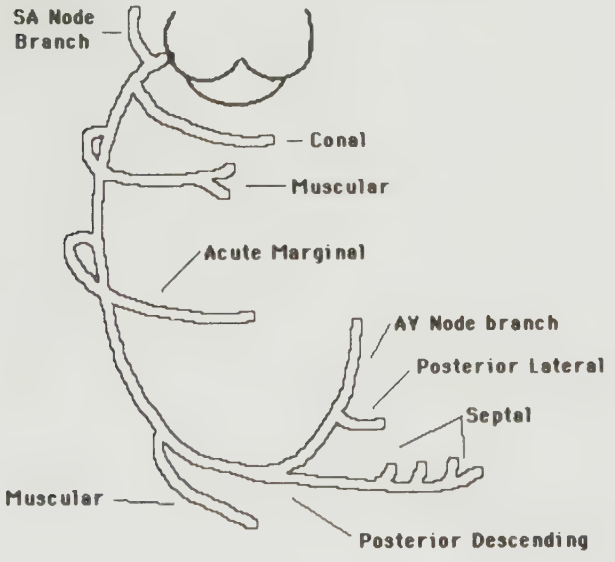

Fig. 83–2. Normal right coronary artery system.

coronary artery in about 50% of cases; in the others, it arises directly from the right aortic sinus of Valsalva. The sinus node artery arises from the right coronary artery in 50% of cases and from the left circumflex artery in the remainder (see above). The right ventricular free wall is supplied by several branches of the right coronary artery. The largest of these branches is the acute marginal branch of the right coronary artery.

As was noted above, 90% of people have a "dominant right coronary artery system." That is, the posterior descending coronary artery is a branch of the right coronary artery. In the remainder, the descending coronary artery originates from the left coronary artery. The term "dominant right coronary artery system" refers only to the origin of the posterior descending coronary artery and not to the coronary artery that supplies most of the myocardium. Indeed, except in unusual circumstances, the majority of the myocardium is supplied by the left coronary artery regardless of the "dominance" of the coronary artery system.

The posterior descending coronary artery supplies the lower portion of the ventricular septum. The septal branches of the posterior descending coronary artery anastomose with the septal branches of the left anterior descending coronary artery. Muscular branches supplying the diaphragmatic portions of the right and left ventricles also arise from the posterior descending coronary artery. The artery to the atrioventricular node originates from the posterior descending coronary artery and travels cephalad to reach the atrioventricular node.

Minor Variations of Normal Coronary Anatomy

Variations in the number of coronary ostia are so frequent that it is difficult to know whether two ostia or three ostia are "normal." In approximately 50% of cases, the right conus artery originates from a separate orifice of the right coronary cusp. A total of three orifices also can occur if the left circumflex coronary artery arises from a separate orifice in the left coronary cusp. Four coronary orifices will be found if there are separate origins of both the right conus artery and the left circumflex coronary artery. In 1 out of 200 cases, the left circumflex coronary artery arises from the right aortic sinus of Valsalva and travels posterior to the aorta to reach its area of distribution.[2] This anomaly can be important during cardiac operation because, if it is unrecognized, the left circumflex can be damaged inadvertently.

The coronary artery ostia usually are located just below the junction of the sinus and tubular portions of the aorta or within 1 cm above this position in adults.[3] Banchi noted that the left coronary artery arose at the level of free margin of the aortic cusp in 48% of cases, above that level in 34%, and below it in 18%.[4] The right coronary artery arose at the level of the free margin of the aortic cusp in 71% of cases, above in 19%, and below in 10%.

MAJOR CORONARY ANOMALIES

Anomalous Origin of the Left Coronary Artery from the Pulmonary Artery

Anomalous origin of the left coronary artery from the pulmonary artery (ALCA) is perhaps the most frequent important coronary anomaly with which pediatricians and pediatric cardiologists must deal. It was described by Brooks in 1886[5] and by Abbott in 1908.[6] Abbott's patient died at 60 years of age. In 1933, Bland, White,

and Garland[7] observed an infant with this anomaly and noted episodes of acute distress in the infant during feeding, presumably a manifestation of acute coronary insufficiency. ALCA occurs in 1 out of 300,000 children and constitutes 0.24% of all congenital cardiac defects.[8]

ALCA most commonly occurs as an isolated malformation. However, it has been associated with ventricular septal defect, endocardial cushion defect, tetralogy of Fallot, and truncus arteriosus.[9–14] In addition to ALCA, the left anterior descending or circumflex coronary artery may arise anomalously from the pulmonary artery.

Usually, the anomalous coronary artery arises from the left pulmonary artery sinus. However, it may arise from the right or left pulmonary artery. There are two theories of embryonic development to explain the occurrence of ALCA.[15] The first implies that the coronary arteries originate from two primordial buds on the undivided conotruncus. As the conotruncus is divided into the aorta and pulmonary artery, abnormally high placement of one of the coronary buds can result in anomalous left coronary artery (Fig. 83–3). Alternatively, abnormal division of the conotruncus can produce ALCA despite normal placement of both primordial buds (Fig. 83–3).[16,17] The second theory implies that six coronary buds or anlagen exist on the primitive truncus arteriosus: one from each potential cusp of the aortic and pulmonary sinuses. Normally, all but two involute; if, for reasons that are unclear, the wrong sequence of persistence and involution occurs, ALCA may result.[18]

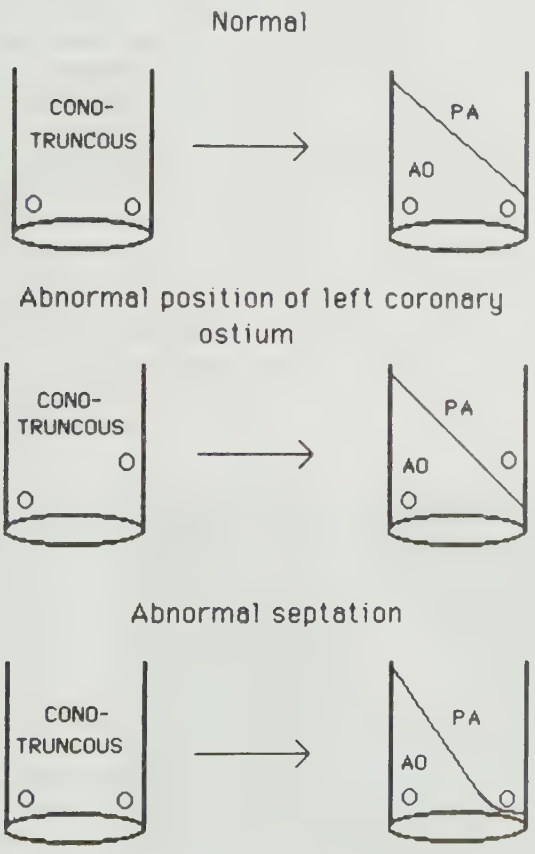

Fig. 83–3. Embryologic origin of anomalous origin of the left coronary artery from the pulmonary artery. If the left coronary artery bud is displaced cephalad, it remains with the pulmonary artery after normal conotruncal division. Alternatively, if the left coronary bud is normally located but conotruncal septation is abnormal, the left coronary artery originates from pulmonary artery. AO = aorta; PA = pulmonary artery. Clinical Manifestations

A patient with ALCA may present with signs and symptoms of myocardial infarction and congestive heart failure in infancy, or the condition may be unassociated with myocardial infarction or symptoms of heart disease and may be detected serendipitously in adulthood or at autopsy. Because of the wide range of clinical presentation and ages at presentation, investigators have divided this anomaly into two types: infantile and adult. Neufeld and Schneeweiss[3] reviewed 460 cases of ALCA reported in the literature and found that 60 (13%) of these patients presented in adulthood. This division may be arbitrary and may obfuscate the pathophysiologic features of this anomaly. The "infantile" and "adult" forms are on opposite ends of the spectrum of ALCA. The location of an individual patient within that spectrum depends on the degree of collateral circulation between the right and left coronary artery systems. Subjects with well-developed collateral connections may not develop myocardial infarction and may do well, but subjects with poor collateral circulation will have myocardial infarction, and this will be apparent at an early age. Indeed, confusion regarding the efficacy of treatment of this condition exists, to a large extent, because the natural history of the anomaly is different for different subsets of patients, and these subsets are probably based on the degree of right and left coronary artery collateral development. Results of treatment may depend on which subsets are selected for which treatment regimens.

In the immediate newborn period, pulmonary artery resistance and pressure are increased, flow through the anomalously arising left coronary artery is antegrade from the pulmonary artery, and myocardial perfusion is adequate. As pulmonary artery resistance and pulmonary pressure decrease, antegrade flow of blood from the pulmonary artery through the left coronary artery decreases. If there is inadequate collateral circulation between the right and left coronary artery, myocardial infarction will likely occur at this time. If collateral circulation exists, myocardial infarction may or may not occur, depending on the degree of retrograde flow from the right coronary system through the collateral circulation and into the pulmonary artery (i.e., coronary steal phenomenon) and the degree of antegrade flow along the distribution of the left coronary artery (i.e., myocardial perfusion).

Patients with ALCA may present in infancy and early childhood with signs and symptoms of congestive heart failure. These include tachypnea, pallor, and poor feeding. As described by Bland, White, and Garland,[7] there may be a history of paroxysms of crying, pallor, diaphoresis, and agitation in infancy, presumably due to acute myocardial ischemia. However, in many cases, these paroxysms are not described. Signs of congestive heart failure are apparent at physical examination. An apical gallop rhythm and a murmur of mitral insufficiency may be heard. Cardiomegaly is apparent on chest radiographs, and the electrocardiogram may reveal evidence of myocardial infarction. (See Chapter 45.) The clinical features of ALCA in infancy are similar to those of myocarditis and cardiomyopathy, and the diagnosis of ALCA must

be considered in the differential diagnosis of unexplained congestive heart failure in infancy.

In teenagers and adults, the presence of ALCA may be suspected on the basis of unexplained cardiomegaly, mitral insufficiency, or a continuous cardiac murmur. Angina may occur secondary to a coronary steal phenomenon.

Before the development of high-resolution, two-dimensional echocardiography and Doppler techniques, angiography was necessary to establish the diagnosis of ALCA. Injection of contrast into the aortic root reveals the origin of only a large right coronary artery from the right aortic sinus of Valsalva (Fig. 83–4). Injection of contrast into the pulmonary artery may reveal the abnormal origin of the left coronary artery, but most frequently it will not be apparent because of lack of antegrade flow from the pulmonary artery to the left coronary artery. The diagnosis also can be inapparent during aortic root angiography. The left coronary artery may fill rapidly from the right coronary artery and may *appear* to originate from the left coronary cusp. If, in addition to anteroposterior and lateral views, left and right oblique views are obtained, it will be apparent that the origin of the left coronary artery is from the pulmonary artery rather than the aorta. Visualization of ALCA can be difficult when it is associated with other intracardiac defects that produce a left-to-right shunt.

With the increasing technical sophistication of two-dimensional echocardiography, ALCA artery can be defined in many cases by using this technique. In addition, Gutgesell, Pinsky, and DePuey[19] found that thallium-201 myocardial imaging was useful in distinguishing patients with myocardial dysfunction and ALCA from patients with cardiomyopathy.

Treatment

The ideal treatment of ALCA would be to detect the presence of this anomaly before myocardial infarction occurs and to establish a coronary system that would prevent myocardial infarction. Unfortunately, all cases in infancy come to medical attention only after myocardial ischemia and infarction have occurred. In addition, as was noted above, because of the wide spectrum of myocardial compromise, it is difficult to assess results of various treatment regimens. It seems clear, however, that infants with ALCA and poor left ventricular function (an ejection fraction less than 20%) do poorly regardless of surgical or medical management at a young age.[20] Second, infants with ALCA and good left ventricular function continue to do well regardless of whether the operation is performed before or after one year of age. Third, occasionally infants who are doing poorly have spontaneous improvement (Fig. 83–5). These observations are important in designing treatment strategies to allow survival of patients with ALCA. Besides survival, however, treatment has to be directed at preservation of myocardial function. In addition, treatment strategies related to early or delayed surgical intervention need to change as surgical techniques improve. With increasing surgical experience to reimplant coronary ostia in infants with transposition of the great arteries (the Jatene procedure), the operative risk of infants with ALCA may decline.

Numerous operative techniques have been described for treatment of patients with ALCA.[14,20,22–25] These include ligation of the left main coronary artery, the Vineberg procedure, subclavian-to-left coronary artery anastomosis, saphenous vein bypass grafting, creation of an aorticopulmonary window and a tunnel to connect the aorta to the orifice of the left coronary artery, and reimplantation of the ostia of the left coronary artery onto the aorta. Ligation of the left coronary artery and the Vineberg procedure are of historical interest only and probably should be abandoned. Although there is limited scientific evidence to support the contention that a two-coronary artery system is superior to a one-coronary artery system, this concept is intuitively reasonable, and attempts to establish a two-coronary artery system for patients with ALCA seem warranted. It is unclear whether or not any one of the above procedures designed to establish a two-coronary artery system is superior to the others. The surgeon should probably use the technique with which he or she is most comfortable.

For children older than one year of age, adolescents, and adults,
